Exploring excited states of Pt(II) diimine catecholates for photoinduced charge separation
Exploring excited states of Pt(II) diimine catecholates for photoinduced charge separation†

Paul A. Scattergood,a Patricia Jesus,b Harry Adams,a Milan Delor,a Igor V. Sazanovich,a,c Hugh D. Burrows,b Carlos Serpa*b and Julia A. Weinstein*a

The intense absorption in the red part of the visible range, and the presence of a lowest charge-transfer excited state, render Platinum(ii) diimine catecholates potentially promising candidates for light-driven applications. Here, we test their potential as sensitisers in dye-sensitised solar cells and apply, for the first time, the sensitive method of photoacoustic calorimetry (PAC) to determine the efficiency of electron injection in the semiconductor from a photoexcited Pt(ii) complex. Pt(ii) catecholates containing 2,2'-bipyridine-4,4'-di-carboxylic acid (dcbpy) have been prepared from their parent iso-propyl ester derivatives, complexes of 2,2'-bipyridine-4,4'-di-Cl(O)Pr, (COOPr)2-bpy, and their photophysical and electrochemical properties studied. Modifying diimine Pt(ii) catecholates with carboxylic acid functionality has allowed for the anchoring of these complexes to thin film TiO2, where steric bulk of the complexes (3,5-di-tBu-catechol vs. catechol) has been found to significantly influence the extent of monolayer surface coverage. Dye-sensitised solar cells using Pt(dcbpy)(tBu2-Cat), 1a, and Pt(dcbpy)(pCat), 2a, as sensitisers, have been assembled, and photovoltaic measurements performed. The observed low, 0.02–0.07%, device efficiency of such DSSCs is attributed at least in part to the short excited state lifetime of the sensitiser, inherent to this class of complexes. The lifetime of the charge-transfer ML/LLCT excited state in Pt((COOPr)2-bpy)(3,5-di-tBu-catechol) was determined as 250 ps by picosecond time-resolved infrared spectroscopy, TRIR. The measured increase in device efficiency for 2a over 1a is consistent with a similar increase in the quantum yield of charge separation (where the complex acts as a donor and the semiconductor as an acceptor) determined by PAC, and is also proportional to the increased surface loading achieved with 2a. It is concluded that the relative efficiency of devices sensitised with these particular Pt(ii) species is governed by the degree of surface coverage. Overall, this work demonstrates the use of Pt(diimine)catecholate complexes as potential photosensitizers in solar cells, and the first application of photoacoustic calorimetry to Pt(ii) complexes in general.

Introduction

Catechol ligands, members of the dioxolene family, have been extensively utilised within the coordination chemistry of various metal ions such as Ru(II),1–8 Os(II)9,10 and Re(I).11–13 The most attractive feature of catechol ligands is their rich electrochemistry, with facile and reversible oxidation to semiquinone and quinone forms, together with the strong interplay between catechol and metal-based orbitals frequently resulting in transition metal complexes which display ‘non-innocent’ behaviour.14,15 Whilst transition metal catecholates have been widely studied, Pt(u) catecholate chemistry has been rather less explored.16–25 Previously reported Pt(u) catecholates commonly feature α,α′-diimines such as substituted bipyridines or phenanthrolines, in conjunction with simple dioxolenes, for example pyrocatechol, 3,5-di-tert-butyl catechol or 4-tert-butyl catechol. These Pt(u)-centred complexes are characterised by the broad, moderately intense, low-energy electronic absorption, being predominantly of a ligand-to-ligand charge transfer nature (LLCT).16,17 Previous investigations have shown the aforementioned electronic transition to involve a HOMO which is primarily catechol-based and a diimine localised LUMO, with ligand substitution having a profound effect upon the electronic and photophysical properties of the complex as a whole.16,21 Catechol ligands have also been utilised to move the lowest energy electronic absorption band of metal complexes into the strategically important near infra-red (NIR)
region, with the first oxidation potential being typically between -0.2 and +0.2 V vs. Fe/C.

The tunable nature of both the photophysical and electrochemical properties of Pt(u) catecholates makes them potential candidates for use within inorganic dye-sensitised solar cells (DSSC’s). These photoelectrochemical devices are centred around a light absorbing ‘dye’ molecule anchored to a thin film semi-conductor surface, commonly TiO2.26,27 The operational principle of these photovoltaic cells involves the injection of electrons from the photo-excited dye into the conduction band of TiO2, thereby producing electrical current, with the oxidised dye being regenerated through electron transfer from a redox electrolyte, commonly I2/I3-. The ability to control and fine tune the electronic properties of the dye is of great importance in ensuring efficient electron injection; in the close matching of electrochemical potentials with those of the redox electrolyte and in tailoring the optical absorbance to cover as much of the solar emission spectrum as possible – particularly the NIR region. Whilst substituted polypyridyl-containing Ru(u) complexes have dominated DSSC research to date, a limited range of Pt(u)-centred systems have been explored. For example, previous reports28-30 introduce a range of dinitre Pt(ii) dithiolates, with these complexes being anchored onto TiO2 surfaces through the bipyridine ligands appended with carboxylic acid functionality. These studies take advantage of the easily tuneable Metal–Ligand-to-Ligand charge transfer (MLCT) transition, with the complexes being subsequently incorporated in DSSCs to give overall device efficiencies (η) typically between 0.1–1.1%. Another report31 describes a range of terpyridine-containing alkynyl-based Pt(u) sensitisers. These systems were found to exhibit intense optical absorption in the visible region and relatively long-lived charge transfer excited states, with overall device efficiencies reaching η ≈ 3.6%.

To the best of our knowledge, the potential of Pt(u) catecholates to function as sensitisers within DSSCs remains unexplored. Here, we introduce two new catecholate-based sensitising dyes and investigate their electrochemical and photophysical properties. The uptake of these species onto TiO2 is evaluated, together with an assessment of their suitability as sensitisers through incorporation within DSSCs and the analysis of current–voltage data.

Electron injection from the dye in its excited electronic state into the conduction band of TiO2 with the formation of a charge-separated state between the oxidised dye and the electron within the conduction band of the semiconductor is one of the most important processes in DSSCs.32 The parameter of particular importance is the quantum yield of electron injection, yet it is the quantity which is the most difficult to determine directly. This value is often estimated from the initial amplitude of fast transient absorption signals;29,33 or determined in absolute terms through the kinetics of the dye emission component quenched by electron injection process,34,35 assuming that electron injection competes only with the decay of the excited state. We employ here an alternative approach, which allows one to directly determine the yields of injection – namely, photoacoustic calorimetry (PAC).36,37 This calorimetric technique monitors the photo-induced pressure waves that result from heat deposition processes. Fast piezoelectric transducers are used to evaluate the magnitude of the detected pressure waves which depend upon the non-radiative processes occurring after light absorption, and on the thermoelastic properties of the materials under study. From the relation between the energy absorbed and the heat released the quantum yields of non-radiative processes can be obtained. In the present application, PAC is used for the detection of pressure waves generated upon conversion of excitation energy into heat as the photoexcited dye injects an electron into the conduction band of the semiconductor. Whilst PAC is commonly employed to study the thermodynamics of photoinduced processes in solution,38 we utilise a front-face set-up to follow electron injection at the TiO2–dye–solvent interface and to ultimately determine the quantum yield of electron injection. Here, the yield of electron injection is estimated by measuring the yield of formation of the long-lived charge-separation between the oxidised sensitizer, and the semiconductor (ϕcs).

Previously, we have demonstrated a successful use of PAC for determining the energy of the charge separated state (Ecs) formed between the oxidised dye and the electron within the conduction band.36,37 We now report new transition metal complexes which intensely absorb light in the visible region of the spectrum, investigate their photophysical properties, and evaluate their potential as dyes for DSSCs using the advanced PAC technique.

**Experimental**

cis-Pt(DMSO)2Cl2 was synthesised following a previously reported procedure.39

**Synthesis of (COO’Pr)bpy**

2,2′-Bipyridine-4,4′-dicarboxylic acid, hereafter dcbpy, (350 mg, 1.433 mmol) was suspended in SOC13 (12 ml) and heated to 85 °C for 48 h. The solvent was removed to leave pale yellow solids which were completely purged of excess SOCl3 under a stream of dry nitrogen for a further hour. The thus obtained acyl chloride functionalised intermediate was then re-dissolved in deaerated 1 : 1 (v/v) toluene–iPrOH (25 ml) and heated to 80 °C for 21 h. Removal of the solvent gave pale yellow coloured solids which were subsequently re-dissolved in CHCl3 (75 ml) and washed with 2 × 75 ml saturated aqueous NaHCO3 solution. The aqueous phases were extracted with a further 1 × 30 ml portion of CHCl3. The combined organic layers were washed with 2 × 50 ml H2O, dried over MgSO4, filtered and the solvent removed to yield the product as an off-white coloured solid. Yield = 379 mg, 81%. 1H NMR (CDCl3, 400 MHz): 1.42 (d, J = 6.28 Hz, 12H), 5.32 (sept, J = 6.28 Hz, 2H), 7.90 (dd, J = 1.32, 4.82 Hz, 2H), 8.86 (d, J = 4.88 Hz, 2H), 8.92 (d, J = 1.12 Hz, 2H). EI-MS: m/z = 328 [M+], 269 [M+ – O’Pr, 42%], 242 (M+ – COO’Pr, 100%).
Synthesis of \([(\text{COO})\text{Pr})_2\text{bpy}]\text{PtCl}_2\) (1)

2,2'-Bipyridine-4,4'-diisopropylacacetate \((\text{COO})\text{Pr})_2\text{bpy}\) (334 mg, 1.017 mmol) and Pt(DMSO)Cl\(_2\) (423 mg, 1.001 mmol) were suspended in deaerated EtOH (40 ml) and heated to 65 °C in the dark for 20 h. The mixture was allowed to cool to room temperature, with the resultant bright orange coloured precipitate being collected by filtration. The solids were washed with EtOH followed by Et\(_2\)O and dried \textit{in vacuo}. Yield = 519 mg, 87%. \(^1\text{H} \text{NMR (CDCl}_3, 400 \text{ MHz})\): 1.48 (d, \(J = 6.28 \text{ Hz, 12H}\), 5.37 (sept, \(J = 6.28 \text{ Hz, 2H}\), 8.05 (dd, \(J = 1.72, 6.05 \text{ Hz, 2H}\), 8.57 (sept, \(J = 1.52 \text{ Hz, 2H}\), 7.93 (d, \(J = 6.00 \text{ Hz, 2H}\), EI-MS: \(m/z = 594 (M^+, 55\%), 508 (M^+ – \text{COO})\text{Pr}, 16\%), 328 (M^+ – \text{PtCl}_2, 14\%), 242 (M^+ – \text{PtCl}_2\text{COO})\text{Pr, 100}\%). Anal. Calc. for C\(_{18}\)H\(_{20}\)N\(_2\)O\(_4\)Cl\(_2\)Pt (%): C 36.19, H 3.31, N 4.57, Cl 11.63. Found: C 36.19, H 3.31, N 4.73, Cl 11.93. Yield = 519 mg, 87%. 1H NMR (d\(_6\)-DMSO, 400 MHz): 6.17 − 7.56 (m, 12H), 8.97 − 9.00 (m, 2H), 14.26 (s broad, 2H). MALDI-MS: \(m/z = 743.2 (M^+\}).

Synthesis of \([(\text{COO})\text{Pr})_2\text{bpy}]\text{Pt}′(\text{Bu})\text{Cat}\) (1a)

Pyrocatechol (59 mg, 0.535 mmol) and \(^{1}\text{BuOK}\) (87 mg, 0.775 mmol) were dissolved in dry, deaerated THF (20 ml) and stirred rapidly at room temperature for 45 min. The deep blue coloured solution was then transferred \textit{via} cannula to \((\text{COO})\text{Pr})_2\text{bpy}]\text{PtCl}_2\) (222 mg, 0.373 mmol) in dry, deaerated THF (20 ml). The resulting reaction mixture was heated to 75 °C in the dark for 48 h. The solvent was removed and the residue purified by column chromatography (SiO\(_2\), slow gradient, 0.1% MeOH – DC\(_2\)M – DC\(_2\)M). After complete removal of all yellow coloured material the product was collected from a deep blue fraction. Removal of the solvent afforded the title complex as a dark blue coloured solid. Yield = 237 mg, 85%. \(^1\text{H} \text{NMR (CDCl}_3, 400 \text{ MHz})\): 1.32 (s, 9H), 6.28 (d, \(J = 1.92 \text{ Hz, 1H}\), 6.50 (d, \(J = 2.08 \text{ Hz, 1H}\), 8.12 (dd, \(J = 1.72, 5.96 \text{ Hz, 1H}\), 8.21 (dd, \(J = 1.68, 5.88 \text{ Hz, 1H}\), 8.97 − 9.00 (m, 2H), 9.38 − 9.43 (m, 2H), 14.26 (s broad, 2H). MALDI-MS: \(m/z = 659.4 (M^+\}).

Synthesis of \([(\text{COO})\text{Pr})_2\text{bpy}]\text{Pt}′(\text{Bu})\text{Cat}\) (1b)

KOH (98 mg, 1.746 mmol) was dissolved in 1 : 1 (v/v) THF–H\(_2\)O (16 ml). The solution was deaerated by bubbling argon for 15 min and then transferred \textit{via} cannula to (1) (45 mg, 0.060 mmol). The resulting deep blue coloured solution was stirred at room temperature in the dark for 3 days. The reaction mixture was acidified (pH 4) through the dropwise addition of 0.1 M HCl, yielding a fine precipitate which was subsequently collected by centrifugation. Purification was achieved by thorough washing with H\(_2\)O, DCM and Et\(_2\)O to leave fine dark blue solids which were dried \textit{in vacuo}. The product was found to be fully soluble in DMF and DMSO only. Yield = 22 mg, 55%. \(^1\text{H} \text{NMR (d}_6\text{DMSO, 400 MHz})\): 1.22 (s, 9H), 1.46 (s, 9H), 6.28 (d, \(J = 1.92 \text{ Hz, 1H}\), 6.50 (d, \(J = 2.08 \text{ Hz, 1H}\), 8.12 (dd, \(J = 1.72, 5.96 \text{ Hz, 1H}\), 8.21 (dd, \(J = 1.68, 5.88 \text{ Hz, 1H}\), 8.97 − 9.00 (m, 2H), 9.38 − 9.43 (m, 2H), 14.26 (s broad, 2H). MALDI-MS: \(m/z = 547.1 (M^+\}).

General information

All synthetic manipulations were carried out under an atmosphere of argon using standard Schlenk line techniques. Dry solvents were obtained from a Grubbs solvent purification column. Deaeration of solvents was performed through the vigorous bubbling of argon for a period of at least 15 minutes.

NMR spectroscopy. All \(^1\text{H} \text{NMR spectra were recorded on a 400 MHz Bruker Avance 400 spectrometer. Deuterated solvents were purchased from Sigma Aldrich and were of spectroscopic grade. Chemical shifts are reported in ppm and calibrated relative to the residual solvent signal (CDCl}_3 7.26 ppm, d\(_6\)-DMSO 2.50 ppm).}

Mass spectrometry. Positive electron ionisation (EI) mass spectra were recorded through the use of a VG AutoSpec magnetic sector instrument. Matrix Assisted Laser Desorption Ionisation (MALDI) mass spectra were obtained from a Bruker Reflex III instrument fitted with a time-of-flight mass analyser, utilising a DCTB matrix.

Elemental analysis. Elemental microanalysis for carbon, hydrogen and nitrogen was performed using a Perkin Elmer
Electrochemistry. Cyclic voltammograms were measured using an Autolab Potentiostat 100 with General Purpose Electrochemical Software (GPES). Analyte solutions were prepared using dry DCM obtained from a Grubbs solvent purification column. Measurements were conducted at room temperature under a stream of dry N₂ at varying scan rates ranging from 20 to 500 mV s⁻¹. N₂Bu₄PF₆ was used as a supporting electrolyte, being recrystallised from ethanol and oven dried prior to use, with a typical solution concentration of 0.2 M. The working electrode was a glassy carbon disc, Pt wire was the counter electrode. The reference electrode was Ag/AgCl, being chemically isolated from the analyte solution by an electrolyte containing bridge tube tipped with a porous frit. Ferrocene was synthetically isolated from the analyte solution by an electrolyte containing bridge tube tipped with a porous frit. Ferrocene was employed as an internal reference, with all potentials quoted relative to the Fc/Fc’ couple.

X-Ray crystallography. Diffraction data were recorded on a Bruker Smart CCD area detector with an Oxford Cryosystems low temperature system. The typical experimental T was 100 K, with an X-ray wavelength of 0.71073 Å. Reflections were measured from a hemisphere of data collection frames, each covering ω = 0.3°. All reflections were corrected for Lorentz and polarization effects and for absorption by semi-empirical methods based on symmetry-equivalent and repeated reflections. The structure was solved by direct methods and refined by full-matrix least-squares on F².

Time-resolved infrared spectroscopy. These studies were conducted at the Rutherford Appleton Laboratory, laser for Science Facility, STFC, UK. The set-up and experimental procedures are described in detail elsewhere.²⁴

Photoacoustic calorimetry, PAC. TiO₂ films were prepared by screen printing one layer of TiO₂ colloidal paste (Ti-Nanoxide HT/SO, Solaronix) onto glass microscope slides and by gradually heating at 125 °C for 10 min, 325 °C for 5 min, 375 °C for 10 min, 450 °C for 10 min and 500 °C for 15 min. A film was dyed with MnTPPS (5,10,15,20-tetrakis(4-sulphonylphenyl)-porphyrinate manganese(III) acetate) for several hours to give an optical density of approximately 0.2 at the excitation wavelength. Separate films were dyed with 1a and 2a from DMF solutions, with optical density at 585 nm (1a) and 526 nm (2a) matching that of the MnTPPS/TiO₂ film. Pulsed laser excitation was achieved by the output of an EKSPLA PG122/SH OPO pumped by the third harmonic of an EKSPLA NL301G Nd:YAG laser at a frequency of 10 Hz. A small fraction of the laser beam was reflected to a photodiode and used to trigger the transient recorder oscilloscope (Tektronix DSA 601, 1 Gs s⁻¹). Photoacoustic waves were detected with a 2.25 MHz Panametrics transducer (model 5676). The photoacoustic wave obtained with the MnTPPS dye was used as photoacoustic reference.²⁶ Typically, 200 PAC waves from the samples (TiO₂ with dye 1a or 2a), reference (TiO₂ with MnTPPS) or background (TiO₂ only) immersed in acetonitrile were recorded and averaged under the same conditions. Four sets of averaged sample and background waves were used for data analysis at each laser intensity, with four laser intensities being used in each experiment by interposing neutral density filters with %T between 26% and 84% in the laser beam.

The PAC experiments measure the pressure wave generated upon conversion of excitation energy into heat, as the electronically excited dye evolves to a long lived charge separated state with the electron located in the conduction band of the semiconductor, and the formation of the dye cation. PAC experiments separate several processes which can contribute to heat deposition into the medium by their characteristic lifetimes. A 2.25 MHz transducer employed in the experiments described here allows one to investigate processes associated with the deposition of heat operating in three “time regimes”:

1) For the processes occurring in the time frame shorter than 10 ns, an integrated amount of heat deposited is recorded;
2) For the processes occurring in the time range between ~10 ns and ~500 ns the kinetics of the heat deposition can be resolved;
3) For the processes occurring on a timescale longer than ~500 ns, no detection of heat deposition is possible.

Dye adsorption studies. Titanium dioxide paste (Ti-Nanoxide HT/SO, Solaronix) was deposited onto a glass slide through the screen printing technique with an area of 1 cm². The resulting films were gradually heated (up to 500 °C). Morphology and thickness of the TiO₂ films (1.2 µm) was analysed by electron microscopy (SEM).

TiO₂ films were immersed in the solutions of the dyes in DMF (50 µM), and UV-Vis absorption spectra taken at selected time intervals, from 20 s to 210 min. The amount of adsorbed dye was monitored as a function of time by measuring the absorbance of the dye-modified TiO₂ films at the wavelength of maximum absorption using a Shimadzu UV-2100 UV-Vis spectrophotometer. Excess dye was removed by rinsing with DMF followed by ether or ethanol before the absorption spectrum was registered. For the de-adsorption studies, the films were in contact with a few drops of NaOH (0.1 M) and then immersed in DMF (3 mL). The total amount of the dye adsorbed on the TiO₂ films was determined through the subsequent measurement of a UV-Vis absorption spectra and use of the solution-phase extinction coefficient.

Cell preparation and measurements. The titanium dioxide paste (Ti-Nanoxide HT/SO, Solaronix) was deposited onto transparent conducting glass (2.2 mm thick, 7 ohm per sq FTO, Solaronix) by the ‘doctor-blade’ technique, giving 1 cm² films with 5 µm thickness. Films were dried at 125 °C for 15 min and then a 2 µm thick layer of TiO₂ paste (Ti-Nanoxide D20/SP, Solaronix) was deposited using a screen-printing method. The double-layered films were gradually heated at 125 °C for 10 min, 325 °C for 5 min, 375 °C for 10 min, 450 °C for 10 min and 500 °C for 15 min.

After cooling, the TiO₂ electrode was further treated with a 40 mM TiCl₄ aqueous solution at 70 °C for 30 min and then calcined at 500 °C for 30 min. When the temperature was reduced to 80 °C, the TiO₂ electrode was immersed into a freshly prepared dye solution for a period of 12 h in the dark. The electrode was rinsed and dried. A thin Pt layer (Pt-Catalyst
T/SP Solaronix) was deposited onto transparent conducting glass by the ‘doctor-blade’ technique and used as the counter electrode. The two electrodes were sealed together using polymer film (25 µm, Solaronix) in a sandwich-type cell. Electrolyte was introduced through holes drilled in the counter electrode, subsequently sealed with microscope slides and polymer film to avoid leakage of the electrolyte solution.

The current–voltage (J–V) curve was measured by a Metrohm Autolab PGSTAT 10 electrochemical analyser using a 150 W Solar Simulator (100 mW cm\(^{-2}\), AM 1.5 G) (Newport Oriel) for illumination. The electrolyte used for performance measurements consists of 0.6 M 1-butyl-3-methylimidazolium iodide, 0.03 M iodine, 0.10 M guanidinium thiocyanate, 0.50 M tert-butyl pyridine in a solution of acetonitrile–valeronitrile (85 : 15 v/v%). The DSSCs were masked to expose only the active area (1 cm\(^2\)) under irradiation for all measurements.

**Results and discussion**

**Synthesis**

The ester-functionalised diimine Pt(II) catecholates 1 and 2 were prepared via a ‘two-pot’ method, whereby the appropriate catechol was first deprotonated with Bu2Cat in anhydrous THF prior to complexation with \(\{\text{COO}^\text{Bu2Cat}\}_{2}\text{bpy}\)PtCl\(_2\). It was noted that carrying out the complexation reaction in alcoholic solvents resulted in loss of the diisopropylacetate functionality through base mediated trans-esterification. For example, performing the reaction in MeOH produced \(\{\text{COOMe}\}_{2}\text{bpy}\)Pt (catechol), with trans-esterification being rapid and quantitative. The resultant Pt(II) catecholate products were readily purified by column chromatography, giving very dark blue coloured solids found to be soluble in the majority of common laboratory solvents. Conversion of 1 and 2 to the corresponding carboxylic acid-containing species (1a and 2a) was effected through KOH mediated hydrolysis in a THF–H\(_2\)O solvent system. The final ‘dye’ molecules 1a and 2a were found to be sparingly soluble in all solvents apart from DMF and DMSO (Fig. 1).

**X-ray crystallography**

Single crystals were grown for the dichloride precursor \(\{\text{COO}^\text{Bu2Cat}\}_{2}\text{bpy}\)PtCl\(_2\) and Pt(II) catecholate 2 (Fig. 2 and 3). The crystal structure of \(\{\text{COO}^\text{Bu2Cat}\}_{2}\text{bpy}\)PtCl\(_2\) reveals the Pt(II) centre to be in a distorted square planar coordination environment, with the bond angle between the two chelating nitrogen atoms and the metal centre N(1)–Pt–N(2) being 80.76°. The 4,4′-substituted-2,2′-bipyridine ligand is close to being planar, with a dihedral angle between the two pyridyl rings of 3.45°. This value is consistent with that measured previously for similar diimine Pt(II) complexes.

Electronic absorption spectroscopy

UV-Vis-NIR electronic absorption spectra for DMF solutions of complexes 1, 1a, 2, 2a and the dichloride precursor \(\{\text{COO}^\text{Bu2Cat}\}_{2}\text{bpy}\)PtCl\(_2\) are shown in Fig. 4. All complexes show an intense absorption band in the region of 300 nm, assigned to \(\pi^*\) intra-ligand transitions localised upon the bipyridine moiety. The spectrum recorded for \(\{\text{COO}^\text{Bu2Cat}\}_{2}\text{bpy}\)PtCl\(_2\) reveals an additional, less intense band centered at 415 nm. This tran-
Solvatochromism of the absorption spectra

The CT nature of the lowest energy absorption band is further verified through solvatochromism. Previously, CT transitions in Pt(II) catecholates have been shown to display negative solvatochromic behaviour; namely, the shift of the MMLL/CT band to a higher energy in both instances, being approximately 1300 cm\(^{-1}\) and 1200 cm\(^{-1}\) above that observed for the parent esters of 1a and 2a respectively.

Solvatochromism of the absorption spectra

Cyclic voltammograms were recorded for CH\(_2\)Cl\(_2\) solutions of 1, 2 and the dichloride precursor \(((COO\text{Pr})_2bpy)PtCl_2\) across the potential range +1.2 to −2.2 V vs. FeC/Fe\(^+\) (Fig. 6).

Reduction. All complexes investigated by cyclic voltammetry were found to display two reduction processes within the potential window shown below in Fig. 6. Based on the \(\Delta E\) values (Table 1), for the dichloride precursor, \(((COO\text{Pr})_2bpy)PtCl_2\), both reductions can be considered fully electrochemically reversible, whereas for the Pt(II) catecholates only the first reduction is attributed to a metal-to-ligand charge transfer (MLCT), a feature observed in [diimine]PtCl\(_2\) type complexes reported previously, where the transition has been more stringently described as a ‘charge transfer-diimine’ owing to the chloride ligands making an appreciable contribution to the HOMO.\(^{12}\) The absorption spectra of the catecholates are dominated by a broad, low-energy band which extends into the NIR region. This band is characterised by Pt(II) catecholates, with its\(^3\) absence in the spectrum of \(((COO\text{Pr})_2bpy)PtCl_2\) allowing primary assignment to a ligand-to-ligand charge transfer (LL/CT).\(^{16,17,20,43}\) However, since the electronic transition between catechol and diimine ligands is known to also involve orbital contributions from the metal centre, the process may be more accurately labelled as a mixed metal–ligand-to-ligand charge transfer (MMLL/CT).\(^{21}\) It is noted that the change in catechol ligand between 1 and 2 is manifest in the electronic absorption spectra. The inclusion of tertiary butyl substituents in 1 is seen to shift the maximum of the low energy CT band by approximately 60 nm below that observed for 2. This is attributed to the weakly electron-donating alkyl groups destabilising the catechol based HOMO, thus reducing the HOMO–LUMO energy gap and the energy of the corresponding transition. It is also observed that hydrolysis of the ester groups results in a shift of the MMLL/CT band to a higher energy in both instances, being approximately 1300 cm\(^{-1}\) and 1200 cm\(^{-1}\) above that observed for the parent esters of 1a and 2a respectively.

Fig. 3 X-ray crystal structure of 2. Deep blue coloured crystals were grown from the slow evaporation of a mixed toluene–CH\(_2\)Cl\(_2\) solution at room temperature. Electrochemically quasi-reversible.
The occurrence of these electrochemical features in all com-
plexes allow the processes to be assigned to the sequential
reduction is electrochemically reversible with the second being
electrochemically quasi-reversible.
The early time dynamics (before 5 ps) are dif-
end the HOMO and HOMO−1 for 1 and 2 reside on the catechol fragment.

Picoscsecond time-resolved infrared spectroscopy
The lifetime of the excited state of 1 in fluid solution was
obtained by TRIR spectroscopy, in the detection range from
1400 to 1800 cm⁻¹. Excitation of a solution of 1 in CH₂Cl₂ with
400 nm, ~50 fs laser pulse lead to instantaneous bleaching of
the ground state IR absorption bands, and the formation of
transient signals across the fingerprint region (Fig. 7).
The early time dynamics (before 5 ps) are difficult to resolve
due to very broad signals around 1600 cm⁻¹, which for similar
complexes were previously assigned to vibrationally hot water
molecules associated with the catechol moiety. After ca. 5 ps,
the spectral dynamics can be satisfactorily described with the
250 (±50) ps lifetime, using global fit analysis. The corre-
ponding kinetic traces and fitting curves are shown in Fig. 7.
The observed spectral features are very similar to those
observed by us previously for other Pt(diimine)(catecholate)

Electrochemically quasi-reversible process. Chemically irreversible under the experimental conditions. From ref. 16.

Oxidation. Two oxidation processes were observed for both
1 and 2, the absence of which in ((COO)Pt₂(bpy)PtCl₂ indicates
that these processes are associated with the coordinated cate-
chol fragments. The first oxidation was found to be electro-
chemically reversible for 1 and quasi-reversible for 2, with the
second process being chemically irreversible in both instances.
Indeed, two such electrochemical oxidations have been readily
observed for Pt(u) catecholates previously, with it being well
established that the former relates to a catechol-to-semi-
quinone conversion and the latter to further oxidation of the
fragment to a quinone form. The influence of the two
weakly electron-donating tertiary butyl groups in 1 is
manifested through the occurrence of the first oxidation at a
marginally more cathodic potential than that observed for 2. It
is concluded that both the HOMO and HOMO−1 for 1 and 2

Dye adsorption on TiO$_2$

Thin films (1.2 μm) of nanocrystalline TiO$_2$ deposited on glass slides were immersed in DMF solutions of dyes 1a and 2a. The resulting intense blue-purple colouration imparted on the TiO$_2$ films affirmed successful dye anchorage, with the corresponding UV-Visible absorption spectra of the surface adsorbed dyes being shown in Fig. 8. The spectra of the surface anchored dyes clearly show a broad band in the region of 575–650 nm and 500–575 nm for 1a and 2a respectively. These absorbance features correspond to the ML/LLCT bands observed in the solution phase spectra, although being notably broadened and blue-shifted in both instances. These spectra highlight one of the most favourable attributes of Pt(II) catecholates – their ability to harvest photons from across a low energy part of the visible region.

Dye loadings were investigated by monitoring the progress of dye adsorption: UV-Vis absorption spectra of the sensitised TiO$_2$ films were collected as a function of immersion time, with the surface being rinsed with DMF and Et$_2$O prior to each measurement to remove the non-adsorbed dye. Typical dye solution concentrations of 50 μM were employed so as to minimise dye agglomeration and reduce surface aggregation. The dye uptake plots for 1a and 2a are shown in Fig. 9. Both curves reveal the very rapid initial uptake of the dyes, with approximately 50% of the maximum observed surface coverage being achieved within the first 25 min immersion time. After this period the rate of dye uptake decreases in both instances. Monolayer surface coverage is determined to be approximately 0.5 × 10$^{-8}$ and 1.2 × 10$^{-8}$ mol cm$^{-2}$ for 1a and 2a respectively.

reached when the rate of change of surface adsorbed dye concentration reaches zero, being observed here after approximately 175 min immersion time for both dyes. Desorption of the dyes with NaOH and use of the solution phase extinction coefficient allows monolayer surface loading to be defined as 0.5 × 10$^{-8}$ and 1.2 × 10$^{-8}$ mol cm$^{-2}$ for 1a and 2a respectively. Allowing for a consideration of the thickness (1.2 μm) of the films used within this study, the magnitude of this loading is comparable with that which has been reported for Pt(n) thiolate dyes, although with longer immersion times being required due to the lower dye solution concentrations utilised here.

With the mode and position of surface attachment being identical for both dyes, the higher loading achieved with 2a is attributed directly to the planar nature of this Pt(n) catecholate. Favourable π–π stacking interactions between the pyrocatechol entities, together with short Pt···Pt contacts, are likely to facilitate the close packing of the dye when adsorbed on a semi-conductor surface. The inclusion of tertiary butyl substituents in 1a affords the dye with a significantly greater steric bulk, thus hindering close surface packing and reducing the maximum possible monolayer surface loading by a factor of approx. 2.5.

Photoacoustic calorimetry (PAC)

MnTPPS adsorbed onto a TiO$_2$ film was employed as a photoacoustic reference, and is defined as a dye which converts all absorbed energy into heat on a time-scale much shorter than that of the time-resolution of acoustic detection. After subtraction of an almost negligible background signal, sample and reference PAC signals were compared, with no mis-match in phase, indicating that the release of heat from the sample also occurs on a time-scale faster than the acoustic detection time-resolution. Table 2 shows the values of photoacoustic wave maxima obtained from PAC performed on 1a and 2a anchored to thin film TiO$_2$, where $\phi$ denotes the fraction of heat released by the sample under study relative to the photo-

Table 2  Photoacoustic experimental data (observed wave maxima) for thin film TiO$_2$ sensitised with dyes 1a and 2a immersed in acetonitrile. The wavelengths of excitation were 585 nm (2.12 eV) and 526 nm (2.36 eV) for 1a and 2a, respectively. The laser energy at 100% power was 50 µJ per pulse. The tabulated data are averaged values of results collected in four independent experiments. The values of $\phi_{cs}$ were calculated using eqn (1) and (2), where $E(D/D^+)_{\text{eqn}}$ was the $E^{1/2}_{\text{cs}}$ vs. S.C.E., estimated error is 10%

| Relative laser intensity/| Dye 1a | | Dye 2a |
|-------------------------|-----------------|-----------------|
| Reference/mV | Sample/mV | $\phi$ | $\phi_{cs}$ | Reference/mV | Sample/mV | $\phi$ | $\phi_{cs}$ |
| 100 | 71 | 58 | 0.92 | 69 | 63 | 0.92 |
| 84 | 63 | 48 | 0.92 | 61 | 48 | 0.92 |
| 52 | 48 | 37 | 0.86 | 46 | 40 | 0.78 |
| 26 | 35 | 28 | 0.93 | 33 | 31 | 0.79 |

Average $\phi$: 0.91

Average $\phi$: 0.79

acoustic reference. The maxima of the photoacoustic waves were observed to be independent of the excitation laser pulse energy, indicating that no bi-photonic processes were occurring under the laser fluences used. From the experimentally obtained $\phi$ values, the quantum yield of formation of the long-lived charge separation ($\phi_{cs}$) between the electron injected in the semiconductor and the oxidised dye can be calculated through eqn (1), where $E_{cb}$ is the energy of the conduction band and $E_{cs}$ is the energy of the charge separated state. $E_{cs}$ itself may be determined from eqn (2). We assume a negligible change in the first (catechol-based) oxidation potential upon hydrolysis of the ester functionality, therefore the measured potentials for the parent ester compounds 1 and 2 (Table 1) are used in eqn (2) and the following analysis.

$$\phi_{cs} = \frac{(1-\phi)E_{cb}}{E_{cs}} \quad (1)$$

$$E_{cs} = E(D/D^+) - E_{cb} \quad (2)$$

The PAC results for (1) and (2) showed signals only for the fast (<10 ns) heat deposition, which were assigned to charge injection and also account for the fast recombination of the injected electron with the oxidized sensitizer that occurs on a time scale less than 10 ns. No signal on the longer timescale was detected, therefore the energy not released as heat is assigned to the formation of the long-lived, $>500$ ns, charge separated state between the sensitizer $S^+$ and the semiconductor (TiO$_2^{2+}$). We stress that this way of estimating the yield of electron injection, through the yield of long-lived charge-separation, does not reflect the instantaneous injection only, but also takes into account the recombination processes on the fast, <10 ns, timescale. Thus the value quoted here is the yield of electron transfer to the semiconductor from the photoexcited sensitizer, which remains after 10 ns time.

Here, we consider that dye sensitised TiO$_2$ electrodes exhibit an exponential density of states extending into the TiO$_2$ band gap. Since a low excitation light intensity leads to a low density of photoionjected electrons, the majority of these electrons will occupy states with energies close to the quasi-Fermi level. Under such condition, the calculation of $E_{cs}$ through eqn (2) with a single value is acceptable. Thus, using a value of $\sim0.34$ V (vs. SCE) for the energy of the TiO$_2$ conduction band ($E_{cb}$)$^{50}$ we obtained values of 0.26 and 0.56 for the yields of long-lived dye-TiO$_2$ charge separation for 1a and 2a, respectively. A control experiment on the dye N719 (cis-bis(isothiocyanato)-bis(2,2’-bipyridyl-4,4’-dicarboxylato)-ruthenium(II)) performed under identical experimental conditions$^{57}$ yielded a 100% quantum yield of the formation of the charge separated state (assuming $E_{cs}$ of 1.05 eV$^{37,51}$ for this dye), which is consistent with the previous results.$^{52}$

It has been reported that the energy of the conduction band ($E_{cb}$) for thin film anatase TiO$_2$ depends upon the nature and composition of a contiguous electrolyte solution$^{53}$ namely upon the presence of cations in the non-aqueous electrolytes,$^{54}$ in addition to the chemical nature of the sensitisers itself.$^{55}$ In this work, PAC studies were performed in neat acetonitrile, and it is therefore possible that the effective position of the conduction band may differ from the value considered above. Values as negative as $\sim 2$ V (vs. SCE) have been reported for TiO$_2$ in contact with acetonitrile.$^{53}$ As a result, the values for the yield of formation of charge separated states estimated using PAC technique should be considered an upper limit.

The observed low dye-to-semiconductor electron injection yields in sensitised TiO$_2$ films (in contact with MeCN) may be accounted for by a short excited state lifetime of the dyes. Results presented previously$^{56}$ have illustrated that a complete sensitised solar cell (including electrolyte) exhibits an approx. 20-fold retardation in the rate of electron injection in comparison to a dye-sensitised TiO$_2$ film. The addition of a redox electrolyte is, therefore, likely to reduce the electron injection efficiency further$^{57}$ and therefore the quantum yields of electron injection determined through PAC (Table 2) may be substantially reduced upon incorporation of the dye into a complete functioning DSSC.

Photocurrent–voltage characteristics of Pt-Dye/TiO$_2$ electrodes

Photovoltaic device performance parameters were obtained for cells sensitised with dyes 1a and 2a (Table 3) with accompanying current–voltage curves generated under illumination with AM 1.5 G (100 mW cm$^{-2}$) simulated sunlight displayed in Fig. 10. It is apparent that cells sensitised with these particular Pt(n) complexes operate with a poor overall efficiency ($\eta$), being somewhat lower than other devices sensitised with Pt(n)
Table 3 Photovoltaic device performance parameters for cells sensitised with 1a and 2a (24 h immersion time). Measurements were taken under AM 1.5 G (100 mW cm\(^{-2}\)) simulated solar light, with a square-shaped mask of area 1 cm\(^2\) being used in all experiments.

Conclusion

Pt(\(ii\)) diimine catecholates which intensely absorb in the red part of the visible spectrum are potentially promising candidates for light-driven applications. Here, we test their potential as sensitisers in dye-sensitised solar cells, and correlate this property with the efficiency of charge separation, evaluated by photoacoustic calorimetry (PAC). Two 2,2’-bipyridine-4,4’-di-carboxylic acid-containing Pt(\(ii\)) catecholates have been prepared from their parent iso-propyl ester derivatives, and their photophysical and electrochemical properties studied. Solution phase electronic absorption spectra show intense charge transfer bands which extend into the NIR region, the energy of which may be readily tuned through substituent variation upon the diimine and catechol ligands. Modifying diimine Pt(\(ii\)) catecholates with carboxylic acid functionality has allowed for the successful anchoring of these complexes to thin film TiO\(_2\), where steric bulk of the donor ligands (tBu-catechol vs. catechol) has been found to significantly influence the extent of monolayer surface coverage. In this instance, 2a bearing an unsubstituted catechol shows a 2.5-fold increase in surface loading over 1a, which contains a bulkier tBu-catecholate ligand. Photovoltaic measurements on solar cells sensitised with 1a and 2a have allowed for an assessment as to the suitability of these complexes as sensitisers. The observed 0.02–0.07% device efficiency is attributed to the short excited state lifetime and rapid charge recombination dynamics inherent to this class of complex. Specifically, the lifetime of the charge-transfer ML/LLCT excited state in the parent complex 1 was determined as 250 ps by time-resolved infrared spectroscopy, TRIR. The measured increase in device efficiency for 2a over 1a is consistent with a similar increase in the quantum yield of the long-lived charge separated state (where the complex acts as a donor and the semiconductor as an acceptor) as determined by Photo-Acoustic Calorimetry, and is also matching the magnitude of the increased surface loading achieved with 2a. It is concluded that the relative efficiency of devices sensitised with these particular Pt(\(ii\)) species is governed by the degree of surface coverage. Overall, this work demonstrates for the first time the use of...
Pt(diimine)(catecholate) complexes as potential photo-sensitizers in solar cells: the intense absorption in the visible/NIR part of the spectrum is a strong advantage of these dyes, whilst the short excited state lifetime can in the future be addressed by modifying the diimine ligands involved.
