Abstract— For accurate fault detection and diagnosis, this paper focuses on the study of bearing vibration responses under increasing radial clearances due to investable wear and different bearing grades. A nonlinear dynamic model incorporating with local defects and clearance increments is developed for a deep groove ball bearing. The model treats the inner race-shaft and outer race-housing as two lumped masses which are coupled by a nonlinear spring formalized by the Hertzian contact deformation between the balls and races. The solution of the nonlinear equation is obtained by a Runge-Kutta method in Matlab. The results show that the vibrations at fault characteristic frequencies exhibit significant changes with increasing clearances. However, an increased vibration is found for the outer race fault whereas a decreased vibration is found for inner race fault. Therefore, it is necessary to take into account these changes in determining the size of faults.

Keywords— radial clearance; contact deformation; condition monitoring; bearing defects

I. INTRODUCTION

A large number of papers have been focused on developing signal processing techniques to detect and isolate faults of bearings with high degree of accuracy. But relatively few studies have presented a mathematical (physics-based) model, where faults can be simulated under different operating conditions rather than waiting for their natural occurrence, or alternatively having them seeded for laboratory testing.

Different mathematical models have been developed to study the dynamic effects on the roller bearing. In 1984, McFadden and Smith developed a model which described the vibration produced by a single point defect on the inner race of a rolling element bearing under constant radial load [1]. Purohit et al. (2006) [2] studied the radial and axial vibrations of a rigid shaft supported ball bearing. In the analytical formulation the contacts between the balls and the races are considered as nonlinear springs, whose stiffness is obtained by using the Hertzian elastic contact deformation theory. Culita et al. (2007) [3] presented the McFadden-Smith vibration model, one of the first valid models of vibration generated by single point defects in bearings. They presented how the defect is encoded by vibration in a more accurate and natural manner than previous models. A significant important contribution was brought by S. Sassi et al. (2007) [4]. They developed a numerical model with the assumption that the dynamic behavior of the bearing can be represented by a coupled three-degree-of-freedom system.

II. DYNAMIC MODEL WITH BEARING DEFECTS

A single ball bearing consists of a number of parts. The description of each component can lead to a simulation model with a large number of degrees of freedom (DOF). The free body diagram of the shaft bearing system is provided in Fig. I. Moreover, the deep groove ball bearing (6206) is the studied bearing. The model of the study bearing system is carried out using springs and lumped masses. The proposed model incorporates the following realistic assumptions and considerations.

- Balls are positioned equi-spaced balls around the shaft and there is no interaction between them.
- There is no slipping of the balls during rolling on the surface of races.
- The mass of the ball is negligible because it is relatively small compared with other bearing parts refer to the Table I.
• The study bearing operates under isothermal conditions.
• Forces act in radial directions along X and Y axes.
• The mass of the inner race is included in the mass of the shaft, and the mass of the housing incorporates the mass of the outer race.
• The shaft-housing under study is modelled using two masses, \( M_s \) and \( M_h \), which yield a 2-DOF system.
• Nonlinear Hertzian contact deformations are considered at the contacts formed between balls and races.
• Damping due to lubricant film is ignored.

The geometric and physical properties of the studied bearing are presented in Table I.

#### A. Load Deflection and Stiffness

Hertzian load deformation relationship is used in calculation of deformation at the contacts formed between ball and races of the bearing under investigation. The used relation is expressed as the following [9]:

\[
Q = K \delta^n
\]  

where \( K \) is the load deflection factor or constant for Hertzian contact elastic deformation, \( \delta \) is the radial deflection or contact deformation and \( n \) is the load deflection exponent, \( n = 3/2 \) for ball bearing and \( 10/9 \) for roller bearing [9].

The stiffness coefficient at the contacts formed between races and the \( i^{th} \) ball are evaluated using the following relation [10, 11]:

\[
K_{i,o} = \frac{2\sqrt{2}E}{3\left(\sum \rho^{\frac{3}{2}}\right)} \left(\frac{1}{\delta^2}\right)^{3/2}
\]  

where \( K_{i,o} \) is inner and outer raceways to ball contact stiffness respectively, \( \sum \rho \) is the curvature sum which is calculated using the radii of curvature in a pair of principal planes passing through the point contact. \( \delta \) is the dimensionless contact deflection obtained using curvature difference (Refer Table 6.1, Rolling Bearing Analysis, Tedric Harris, Fourth Edition, 2001).

Total deflection between two raceways is the sum of the approaches between the rolling elements and each raceway [9], hence,

\[
K = \left(\frac{1}{(1/K_i)^{3/2}} + \frac{1}{(1/K_o)^{3/2}}\right)^{-3/2}
\]

Fig. 2 shows the rigidly supported bearing subjected to radial load, the radial deflection at any rolling element angular position is given by [9]:

\[
\delta_r = \delta_i \cos \phi - \frac{1}{2} P_d
\]

where \( \delta_i \) is the ring radial shift, occurring at \( \phi = 0 \) and \( P_d \) is the diametric clearance.

If \( \phi_0 \) is the initial position of the \( i^{th} \) ball, the angular position \( \theta_i \) at any time \( t \) is defined by the following relation:

\[
\phi_i = \frac{2\pi}{N_b}(i - 1) + \omega_c t + \phi_0, \quad i = 1, ..., N_b
\]

where the angular velocity \( \omega_c \) of the cage can be expressed in terms of angular velocity \( \omega_a \) of the shaft as:

\[
\omega_c = \left(1 - \frac{D}{d_m} \frac{\omega_s}{2}\right), \quad \omega_s = 2\pi f_s
\]

The radial deflection at any rolling element angular position may be rearranged in terms of maximum deformation as follows:

\[
\delta_r = \delta_{ma} \left[1 - \frac{1}{2e}(1 - \cos \theta_i)\right]
\]
where \( \varepsilon = \frac{1}{2} \left(1 - \frac{P_d}{2 \delta_c} \right) \)

Therefore, the contact force at any angular position is

\[
Q_\phi = Q_{max} \left[1 - \frac{1}{2 \varepsilon} \left(1 - \cos \phi \right) \right]^{3/2}
\]  (8)

In Fig. 3 it is clear that the overall applied radial load \( F \) is equal to the sum of the vertical components of the contact reactions of the rolling element loads. Mathematically, it is expressed as follows:

\[
F = \sum_{\phi=0}^{\phi=\pi} Q_\phi \cos \phi
\]  (9)

The overall contact deformation \( \delta \) for the \( i \)th ball is a function of the shaft displacement relative to the housing in the radial direction, ball position \( \theta_i \) and the clearance \( c \) is provided by following expression.

\[
\delta = \left( X_s - X_b \right) \cos \theta_i + \left( Y_s - Y_b \right) \sin \theta_i - c
\]  (10)

where \( c = F_d/2(1 - \cos \phi) \) is the internal radial clearance.

Since the Hertzian forces arise only when there is a contact deformation, the springs are required to act only in compression. In other words, the respective spring force comes into play when the instantaneous spring length is shorter than its unstressed length (the terms of \( \delta \) should be positive), otherwise the separation between ball and raceway comes into play and the restoring force is set to zero.

At the time of impact at the defect, a pulse of short duration is produced and it is accounted for by the term \( \Delta \) additional deflection. Hence the expressions for \( \delta \) is modified as:

\[
\delta = \left( X_s - X_b \right) \cos \theta_i + \left( Y_s - Y_b \right) \sin \theta_i - c - \Delta
\]  (11)

The total restoring force is the sum of the restoring force from each of the rolling elements. Thus the total restoring force components in the \( X \) and \( Y \) directions are

\[
F_X = \sum_{i=1}^{N_b} K \left[ \delta_i \right]^{3/2} \cos \theta_i
\]  (12)

\[
F_Y = \sum_{i=1}^{N_b} K \left[ \delta_i \right]^{3/2} \sin \theta_i
\]  (13)

**B. Internal Clearance**

Internal radial clearance is the geometrical clearance between the inner race, outer race and ball. Radial clearance is the play between the ball and raceway perpendicular with the bearing axis. The internal clearance will significantly influence heat, vibration, noise, and fatigue life. For best rolling element bearing life and machine reliability, internal clearance at running conditions must be close to zero [9, 12]. Moreover, it is also necessary for the purpose of diagnosis to gain the knowledge of changes on the characteristic features when the clearance becomes large due to investable wear during the bearing service life.

The angular contact ball bearings are specifically designed to operate under radial and thrust load, and the clearance built into the unloaded bearing angle. In addition, there are five clearance groups, namely C2, C0 (Normal), C3, C4 and C5. Therefore, the radial internal clearances for radial contact deep groove ball bearing (6206) are presented in Table II [9].

**C. Equation of Motion**

Based on the assumption made, the governing equations for each mass in shaft and housing in \( X \) and \( Y \) directions can be developed. According to the motion direction in Fig. 1, the equations are:

\[
M_s \ddot{X}_s + C_s \dot{X}_s + K_s X_s = \sum_{i=1}^{N_b} K \left[ \delta_i \right]^{3/2} \cos \theta_i + F = 0
\]  (14)

\[
M_s \ddot{Y}_s + C_s \dot{Y}_s + K_s Y_s = \sum_{i=1}^{N_b} K \left[ \delta_i \right]^{3/2} \sin \theta_i = 0
\]  (15)

\[
M_b \ddot{X}_b + C_b \dot{X}_b + K_b X_b - \sum_{i=1}^{N_b} K \left[ \delta_i \right]^{3/2} \cos \theta_i = 0
\]  (16)

\[
M_b \ddot{Y}_b + C_b \dot{Y}_b + K_b Y_b - \sum_{i=1}^{N_b} K \left[ \delta_i \right]^{3/2} \sin \theta_i = 0
\]  (17)

**D. Local Defect**

1) Defect on the Inner Race

The location of defects on the inner race does not remain stationary since the inner race rotates at the speed of the shaft \( \omega_s \). Thus, the defect angle for the inner race \( \alpha_{in} \) is defined as:

\[
\alpha_{in} = \omega_s t \pm \left[ W_{defect} / d_i \right]
\]  (18)

Figure 4. Additional deflection of ball due to defect on inner race
The rolling ball approaches the defect either in the loaded zone or the unloaded zone, therefore, the deflection \( \delta \) of the \( i \)th ball varies. Additional deflection at the defect \( \Delta \) of the ball when it passes through the defect is defined by the width of the defect as following:

\[
\Delta = \left( D/2 - D/2 \times \cos(0.5\theta_{\text{ball}}) \right)
\]

where \( \theta_{\text{ball}} = \) width of the defect / radius of the ball.

The position of the \( i \)th ball in the defect zone is mathematically defined as:

\[
(\phi_i - W_{\text{defect}} / d_i) \leq \phi_i \leq (\phi_i + W_{\text{defect}} / d_i)
\]  

2) Defect on the Outer Race

The defect on the outer race is located at an angle \( \alpha_{\text{out}} \) from the \( X \) axis. The local defects on the outer race are normally found in the loaded region. Moreover, the stationary outer race means that the position of the defect usually does not change. Whenever a ball passes over the defect location, it has additional deflection \( \Delta \).

The angular position of \( i \)th ball passing the defect zone is mathematically defined by the following relation:

\[
(\alpha_{\text{out}} - W_{\text{defect}} / d_i) \leq \phi_i \leq (\alpha_{\text{out}} + W_{\text{defect}} / d_i)
\]

![Figure 5. Additional deflection of ball due to defect on outer race](image)

III. DIAGNOSTIC FEATURES WITH CLEARANCE

The above equations (14-17) are second order nonlinear differential equations. To solve these equations each of the second order equations is converted into two first order differential equations. The Runge-Kutta method is used to solve the first differential equation set in Matlab environment.

A. Initial Conditions

The governing equations of motion are solved based on the ball positions (5) and the deflection relation (11) at each step of time. Displacement in \( X \) and \( Y \) directions and velocity \( \dot{X} \) and \( \dot{Y} \) at time \( (t + dt) \) are calculated. The time step \( dt \) of 6 \( \mu s \) for nine cycles has been considered. The initial displacements and velocities in \( X \) and \( Y \) directions are set to zeroes.

The shaft speed of 1500 rpm (25 Hz) with 1000 N radial load is considered as the normal operating condition of the bearing. Two defect sizes with width 0.6 mm and 2.0 mm on both the inner race and outer race will be studied subsequently, which are denoted as small and large faults respectively. The details of the calculation process are summarized in the flow chart of Fig. 6.

![Figure 6. The flow chart of calculation process](image)

B. Diagnosis of Outer Race Defect

The defect on outer race often occurs in loading zone and will have a constant angular position, usually corresponding to the applied direction of the external loading. Therefore, when a moving ball approaches to the defect same magnitude of impulse is expected for every time of contact between ball and defect. On the other hand, the defect my also appear at the start of loading zone due to poor lubricant conditions. Therefore, two outer race defect locations (0 degree and 320 degree s) have been examined for two defect widths 0.6 mm and 2.0 mm under four incremental different clearance values 1, 10, 30 and 60 \( \mu m \).

1) Outer Race Defect at 0 Degree

Fig. 7 presents vibration displacements of the housing in \( X \) direction for baseline, small defect and large defect when the clearance values are at 1, 10, 30 and 60 \( \mu m \). It can be seen that the baseline case, where is no defect on the races, exhibit a clear increase in vibration displacement with clearance increments, showing that the amplitude of local becomes higher with larger clearances. Moreover, for the two defect cases, the periodic vibration amplitudes also show significant increases with clearances and large defect have higher amplitudes.

![Figure 7. Housing displacements in X direction](image)
To show the impact behavior, Fig. 8 shows the vibration velocities of housing in X direction of baseline, small defect and large defect at four different clearance values. For the baseline case, clear increase in vibration velocity amplitude can be seen as result of clearance increases. For the defect case, the impulse caused by the contact between ball and defect is repeated each 40 degrees. Moreover, both the impulse magnitude and duration increase with the defect size.

The frequency spectra of housing acceleration in X direction of baseline, small defect and large defect cases are illustrated in Fig. 9. For the baseline the loading frequency which is the cage frequency multiply by the number of balls can be clearly appeared. For the defect case, the calculated ball pass frequency outer race (BPFO) is 89.8Hz. The fault feature frequency and its harmonics are obviously obtained. Moreover, the increase of the defect acceleration magnitude is caused by the defect size and nonlinear deflection.

$$BPFO = \frac{N_i}{2} f_C (1 - \frac{D}{d_m} \cos \phi)$$  \hspace{1cm} (22)

The acceleration amplitudes of housing in X direction of baseline, small defect and large defect cases are shown in Fig. 10. For the baseline case, the loading frequency amplitude is increased owing to large clearances. For the defect case, the BPFO magnitude and its harmonics are increasing with the increase of the clearance values. Additionally, the magnitude of the BPFO of the small defect is greatly affected by the loading frequency.

2) Outer Race Defect at 320 Degrees

The vibration acceleration amplitudes of defective outer race at 320 degrees in X direction of small defect and large defect cases are shown in Fig. 11. The magnitude of the BPFO is greatly affected by the loading frequency. Furthermore, the BPFO magnitude and its harmonics are decreased with the increase of the clearance values.

C. Diagnosis of Inner Race Defect

Rotating inner race defect generates a complicated vibration signal due to rotation of both defect and balls. The amplitude of the inner race defect is not constant due to the varying load on ball and defect contacts.

Vibration displacements of the housing in X direction at four different clearance values of small defect and large defect cases are presented in Fig. 12. As the rolling ball approaches the defect either in the loaded zone or the unloaded zone the periodic vibration amplitudes show significant variation.
amplitude is decreasing with the increase of the clearance value. For the large defect, the third harmonic amplitude is greatly affected by the system frequency response.

IV. CONCLUSION

A dynamic model for deep groove ball bearings considering internal radial clearance as well as localized defects on inner and outer races is developed to obtain the vibration responses for bearing diagnosis. The bearing is modelled as a 2-DOF system, vibrations of shaft and housing in X and Y directions are studied. The vibration acceleration amplitudes and frequencies are simulated by solving the coupled nonlinear equation of motions using Matlab.

The model predicts that the vibration responses increase with internal radial clearances which will become large during bearing service period due to inevitable wear. As expected, the large the clearance the higher amplitude of the diagnostic feature for the outer race defects. In addition, the defect at loading zone produces higher amplitude.

However, the large clearance reduces the amplitudes of the feature for inner race defects. Therefore, the severity of inner race fault needs to be determined by taking into account bearing service duration and bearing grades.
