22 Graphical Abstract

23

24

25 Highlights

- 26 • No form changes in ibuprofen after SDI run
- 27 • Decrease in intrinsic dissolution rate of ibuprofen from 10 min to 20 min
- 28 • Post-flush effective in removing trapped air bubbles
- 29 • Surface parameters generated by variable-focus microscope showed key trend with
- 30 intrinsic dissolution values seen from UV-imaging

31

32

33 **Abstract**

34 This work reports a novel approach to the assessment of the surface properties of compacts used in
35 Surface Dissolution Imaging (SDI). SDI is useful for determining intrinsic dissolution rate (IDR),
36 an important parameter in early stage drug development. Surface topography, post-compaction and
37 post-SDI run, have been measured using a non-contact, optical, three-dimensional microscope
38 based on focus variation, the Alicona Infinite Focus Microscope, with the aim of correlating the
39 IDRs to the surface properties. Ibuprofen (IBU) was used as a model poorly-soluble drug. DSC and
40 XRD were used to monitor possible polymorphic changes that may have occurred post-compaction
41 and post-SDI run. IBUs IDR decreased from 0.033 mg/min/cm² to 0.022 mg/min/cm² from 10 to 20
42 min, respectively, during the experiment. XRD and DSC showed no form changes during the SDI
43 run. The surface topography images showed that a distinct imprint was embossed on the surfaces of
44 some compacts which could affect IDRs. Surface parameter values were associated with the SDI
45 experiments which showed strong correlations with the IDR values. The variable-focus microscope
46 can be used as a complimentary tool in the determination of IDR values from the SDI.

47 **Keywords:** Ibuprofen; Intrinsic dissolution rate; Surface dissolution imaging; Alicona infinite
48 microscope; Surface roughness; Polymorphism.

49 **Abbreviations:** IBU, Ibuprofen; USP, United States Pharmacopeia; SDS, Sodium dodecyl sulphate;
50 DSC, differential scanning calorimetry; XRPD, x-ray powder diffraction; IDR, Intrinsic dissolution
51 rate; SDI, Surface dissolution imaging; API, Active pharmaceutical ingredient.

52

53

54

55

56 **1. Introduction**

57 Intrinsic dissolution rate (IDR) is an important parameter determined in early stage drug
58 development that helps to predict API in vivo behaviour. The crystallites of the compounds
59 orientate less randomly during their compression and although it is suggested that the preferred
60 orientation of crystallites has a weak correlation with its IDR, it is something that must be
61 considered during accurate dissolution studies (Löbmann et al., 2014; Techno et al., 2007). Cornell
62 et al. 1974 showed that the different faces of crystals depending on their sizes have different
63 contributions to the total surface area and hence their dissolution which means some faces
64 dissolving more quickly than others. Macpherson et al. (1996) also determined the kinetics and
65 mechanism controlling dissolution from the (100) cleavage face of potassium bromide single
66 crystals in acetonitrile using a novel integrated electrochemical/AFM probe and a scanning
67 electrochemical microscope. Other authors have looked at milling, anisotropic surface energetics
68 and wettability of paracetamol crystals (Heng et al., 2006; Heng et al., 2006a). The Surface
69 Dissolution Imaging (SDI) instrument with Actipix™ Technology (Sirius Analytical, Forest Row,
70 UK) offers a compound sparing approach requiring typically 5 - 10 mg of API and an experimental
71 run time of 20-30 min in determining the IDR of an API. Several authors have used the SDI in
72 monitoring IDRs of APIs (Niederquell and Kuentz, 2014; Boetker et al., 2013; Gordon et al., 2013;
73 Hulse et al., 2012; Qiao et al., 2013) as well as in other applications (Ostergaard, et al., 2014, 2010;
74 Ye & Yaghmur, 2011) but to date there has been no work looking at how the surface properties of
75 materials can impact the IDR values obtained. The Alicona™ microscope (Alicona Imaging GmbH,
76 Graz, Austria) is a non-contact optical 3D micro-coordinate measurement and surface texture
77 assessment instrument which operates on the focus variation principle. The technology is typically
78 used for quality assurance in micro-precision manufacturing (Walton et al., 2016; 2015; 2014) and
79 is capable of acquiring topographic surface height data in profile (2D) and areal (3D) formats along
80 with true colour surface images. This work reports on the novel use of the Alicona™ instrument to

81 assess the topography of compact surfaces post-compaction and post-SDI run with the objective of
82 standardising SDI procedures and thus providing consistency in IDR determination.

83

84 **2. Materials and Methods**

85 Ibuprofen (commercial IBU or bulk powder) and sodium dodecyl sulphate (SDS) were purchased
86 from Sigma (UK).

87 The SDI with with Actipix™ Technology (Sirius Analytical, Forest Row, UK) was used in the
88 determination of IDR. The IDR values are calculated using the software which takes the nominal
89 area of the disk used into consideration. A consistent mass of API (5 mg) was used for each
90 compact (compact holder inner diameter is 2 mm and height 2.4 mm) and the torque was applied
91 using a set number of turns of the Allen key.

92 A 1% w/v SDS solution was used as dissolution medium at a flow rate of 0.2 mL/min at 37 °C
93 applying a wavelength of 214 nm. The molar extinction coefficient of IBU was experimentally
94 determined to be $7596.5 \text{ M}^{-1}\text{cm}^{-1}$ with an r^2 value of 0.9925 using a concentration range of
95 0.000005 - 0.001 M. Samples were run for 10 or 20 min. Experiment were conducted in triplicates.

96 Prior to surface assessment with a x5 objective lens on the focus variation microscope (Alicona™
97 microscope (Alicona Imaging GmbH, Graz, Austria), the SDI compacts were dried in an oven at a
98 constant temperature of 40 °C for 20 min to offset any adverse optical effects from liquid films.

99 This procedure was conducted for all compacts post-compaction, post-flush on SDI, post-10 min
100 run and post-20 min run. The obtained images were analysed using the Surfstand™ software

101 (Taylor Hobson,UK, and University of Huddersfield, UK). A schematic representation of the zoom
102 analysis of the compact surface and a software view are shown in Figure 1. The significant
103 parameters used in describing compact surfaces were; highest peak (S_p), lowest valley (S_v), distance
104 between the highest and lowest points (S_z) (Figure 1c shows S_z determination) and the developed
105 interfacial (surface) area ratio (S_{dr}). The developed interfacial area ratio is a measure of the true

106 surface area of the textured sample compared to that of a uniform flat surface. It is expressed as a
107 percentage by which the true measured surface area exceeds that of the nominal uniform
108 measurement area. S_{dr} was calculated from equation 1.

109
$$S_{dr} = \frac{(Texture\ Surface\ Area) - (Cross\ Sectional\ Area)}{Cross\ Sectional\ Area}$$
 Equation 1

110 SDI compacts after variable focus microscopy, were scanned from 5° to 100° 2theta at a rate of 1.5°
111 min⁻¹ using a Bruker D2 Phaser benchtop x-ray powder diffractometer. The bulk powder was
112 analysed using a plastic well plate. For analysis of the compacts, the powder held in the stainless
113 steel cup was directly placed on a silica wafer, spread out using a spatula and directly analysed.
114 This technique was implemented due to the small amount of powder contained in the stainless steel
115 cup. All samples were analysed by differential scanning calorimetry (DSC822E, Mettler-Toledo,
116 Switzerland) after XRPD analysis using standard aluminium pans (40 µL) with a vented lid. The
117 pans were heated from 25 to 220 °C at a rate of 10 °C/min while purging using nitrogen gas. The
118 enthalpy, onset temperatures and melting points of the samples were obtained (a detailed account of
119 the material and method section can be found in the supplementary section).

120

121 **3. RESULTS AND DISCUSSION**

122 The post-flush images highlight how effective the system is at removing trapped air bubbles
123 (indicated by black arrows) shown in Figure 2a. The post-flush images also indicate that dissolution
124 is occurring to some extent before the experiment is recorded. During the 10 min run (Figure 2b), a
125 significant ‘wave’ was seen above the usual jet stream (indicated by red arrow). Wave development
126 may be a consequence of several processes such as removal of surface particles, erosion of layers of
127 the compact caused by lamination and the surface of the compact itself causing disturbance in the
128 laminar flow of the system. The sample run at the 20 min time period (Figure 2c) also resulted in
129 wave generations (indicated by orange arrow) in the jet stream, similar to the 10 min. Figure 2d

130 shows a representative IDR v time graph for a 10 min SDI run. The significant wave resulted in
131 relatively bigger error margins in the 2-4 min region thus highlighting the objective of standardising
132 SDI procedures to provide consistency in IDR determination. As indicated in figure 2 and table 1,
133 IDR decreased over time. The IDRs given in table 1 were calculated using the nominal area of the
134 flat disk ($A = 3.14 \text{ mm}^2$). Also, as discussed below, the errors due to surface roughness and area
135 changes during dissolution are inherently associated with these values. The focus of this current
136 work was the investigation of the relationship between the relative changes in surface
137 area/roughness and IDR. As such, the authors did not investigate and compare IDR values extracted
138 from the images and from effluent data. This subject remains underexplored presumably because
139 the main interest, at least in an industrial setting, is rank ordering of compounds with respect to
140 dissolution performance and to a lesser extent the absolute IDRs. A few studies however, have
141 addressed the quantitative performance of the SDI system in terms of IDR determination. The level
142 of agreement however has been variable depending drug compound in question (Madelung et al.,
143 2017; Ostergaard et al., 2014; Boetker et al., 2013).

144 XRPD (Figure 3a) and DSC (not included) confirmed no changes had occurred to the IBU during
145 the compaction and SDI run processes. The compaction process however, increased the crystallinity
146 of the bulk IBU powder. Figure 3b also shows the scanning electron microscopy (SEM) image of
147 depicting the crystal habit of the ibuprofen crystal. The post-compaction images (Figure 4a) from
148 the focus variation microscope highlight two key observations. The first was that some amount of
149 the IBU powder had been compacted on to the steel rim (Figure 4a, highlighted by the red arrow)
150 with the second being that a distinct imprint of the die remained on the compacts surface (indicated
151 by blue arrow). The consequences could be increased disruption of flow within the SDI and the
152 dissolution of the API from the rim first rather than the surface of the compact. In the post-flush
153 images (Figure 4b), it can be seen that excess API has been removed from the steel rim surrounding

154 the compact and that dissolution had occurred to some extent, increasing the valley depth on the
155 surface.

156 The S_{dr} value of 0.03 for the post compaction compact indicates a closer similarity to the true plane
157 of the surface area that should be produced by the uniform flat surface. The post flush process
158 increases the S_{dr} value to 0.50 and this can be reflected in the increase of the highest peak (Sp) and
159 lowest valley (Sv) (Table 1) causing a significant increase in the distance between the highest peaks
160 and lowest valley (68 to 423 μm). This key trend was evident for the 10 and 20 min sample also.
161 There is a gradual decrease in area from the post flush samples up to the 20 min sample for all the
162 surface parameters measured. The calculated surface properties again at the 10 min and 20 min SDI
163 runs shows a key trend with the IDR values. The SurfstandTM images of representative compacts of
164 IBU in figure 5 relate to Table 1 and confirm the changes in the surface parameters. Figure 5a
165 shows the relatively smoother surface post compaction with figure 5b showing the relatively
166 rougher surfaces and increased surface area as a result of the post-flush. The darker blue valleys in
167 figure 5b and c could account for the significant wave seen in the jet stream in Figure 2. Figure 5d
168 shows the surfaces becoming smoother post the 20 min run. The ability to determine these
169 parameters therefore offers an insight into how surface changes of the compact relate to IDR
170 measurements in trying to get consistent values.

171

172 **4. CONCLUSIONS**

173 XRD and DSC showed no changes to occur in the IBU compacts post SDI runs. IDR values
174 decreased for IBU as the length of the run was increased from 10 min to 20 min. The focus
175 variation microscopy revealed that changes occurring on the compact surfaces paralleled changes in
176 IDR values. It showed a decrease in surface area of the compacts from post-flush to the 20 min run
177 related to a decrease in the IDR values. The ability to determine these parameters therefore offers an

178 insight into how surface changes of the compact relate to IDR measurements and could further
179 impact decisions made in the preformulation stage of drug discovery.

180

181 **5. ACKNOWLEDGEMENTS**

182 The authors would like to acknowledge the University of Huddersfield for financial support and
183 Paul Whittles of Sirius Analytical for the kind use of the SDI instrument.
