Such Intellectual Property Rights and Reproductions cannot and must not be made available for use without the prior written permission of the owner(s) of the relevant Intellectual Property Rights and/or Reproductions.

Declaration of Authorship

I, Katharina DULIAS, declare that this thesis titled, "ARCHAEOGENETICS AND PALAEOGENETICS OF THE BRITISH ISLES" and the work presented in it are my own. I confirm that:

- This work was done wholly or mainly while in candidature for a research degree at this University.
- Where any part of this thesis has previously been submitted for a degree or any other qualification at this University or any other institution, this has been clearly stated.
- Where I have consulted the published work of others, this is always clearly attributed.
- Where I have quoted from the work of others, the source is always given. With the exception of such quotations, this thesis is entirely my own work.
- I have acknowledged all main sources of help.
- Where the thesis is based on work done by myself jointly with others, I have made clear exactly what was done by others and what I have contributed myself.

Doctor of Philosophy

ARCHAEOGENETICS AND PALAEOGENETICS OF THE BRITISH ISLES

by Katharina DULIAS

Although it is well known that different waves of migration have shaped the population of the British Isles through time, little is known about these population movements over the past 12,000 years. This time period includes the recolonisation of the British Isles by the first hunter-gatherers, and the subsequent arrival of the Neolithic peoples, to the Roman conquest and Anglo-Saxon and Viking migrations, all of which have shaped the genetic diversity of the modern population. However, although these population movements are seen in the archaeological and historical record, it is mostly unknown to what extent different populations arrived into Britain, or from where exactly they originated. The timing and scale of these events are as unknown as what became of the indigenous populations. The recent advance of high-throughput DNA sequencing, especially in the field of ancient DNA, together with the increased number of genome-wide sequencing data of ancient humans from various regions and eras, makes larger scale studies of specific ancient populations, such as those of the British Isles, possible. These new techniques now make it feasible to generate considerable amounts of data from large sample sizes of archaeological human remains, allowing questions to be addressed at population level. The use of uniparental markers (mtDNA and Y-chromosome) at high resolution can show a fine-scale picture of the genetic diversity and origin of ancient and modern-day populations of the British Isles, and add to the information gained through genome-wide sequencing. My project highlights population turnover during the Neolithic to Bronze Age transition, in the Scottish Isles, identifies possible Near Eastern/North African ancestry in a Bell Beaker individual from northeastern England, answers questions about the kin relationship between individuals in an Iron Age cave burial in Scotland and within cemeteries from the Bronze

Age, Iron Age and the post-Roman era, and shows the differences in mitochondrial and Y-chromosome haplogroup frequencies across different time periods to the modern-day British population. The provided time-resolved data has allowed analysis of distinct migrations to the British Isles and the genetic composition of its populations throughout different time periods.

Acknowledgements

First of all, I would like to thank Dr. Ceiridwen J. Edwards for her marvellous supervision and support over the last years, as well as Professor Martin Richards for being my co-supervisor and all the insightful discussions. I learned a lot from you.
I also thank Dr. Maria Pala for her co-supervision and input on the modern DNA analysis of this project.
My profound gratitude goes to Dr. Jarek Bryk and Professor Dan Bradley for all their comments and suggestions.
I am very grateful for the time I could spend at the Molecular Population Genetics Group of the Smurfit Institute of Genetics at Trinity College Dublin, especially Dr. Valeria Mattiangeli for her time and dedication for ancient DNA extraction from bones.
I want to thank Steven Birch (University of Aberdeen), Prof. Dame Sue Black (Lancaster University), Prof. Andrew Chamberlain (University of Manchester), Garrard Cole (UCL), Bob Kenyon, George Kozikowski (West Coast Archaeological Services Scotland), Hazel Moore (Environment and Archaeology Services Edinburgh), Jenny Murray, Prof. Dominic Powlesland (University of York), Dr. Clive Waddington (Archaeological Research Services) and Graeme Wilson (Environment and Archaeology Services Edinburgh) for the contribution of ancient samples, as without you this work would not have been impossible.
I thank Dr. Peter Ditchfield (University of Oxford) for undertaking the dietary stable isotope analysis and radiocarbon dating.
I thank Drs. Francesca Gandini (University of Huddersfield), Pedro Soares and Teresa Rito (both University of Minho, Braga) for all their work on the phylogenetic trees, Prof. Jim Wilson (University of Edinburgh) for the provision of modern samples from the British Isles, Prof. David Reich (Harvard Medical School) for his collaboration on the post-Roman and Saxon samples, Dr. Antonia Flaquer (Ludwig-Maximilians University Munich) and Prof. Walther Parson (Innsbruck Medical University) for the provision of modern samples from Germany and the Netherlands.
I would like to thank the Leverhulme Trust Doctoral Scholarship programme to fund my doctorate degree.
I thank Dr. Rui Martiniano for his tremendous help with the bioinformatic analysis, as well as Dr. Lara Cassidy. You have made my life much easier!
My profound gratitude goes to Dr. Stefano Vanin! You have been an amazing advisor and your support, especially in the most discouraging moments,

over the last three years, was very much appreciated.
I want to thank M. George B. Foody for his incredible patience whenever I was fighting with programming and for always helping me out. Your support means a lot to me.
Dr. Cooper Grace, I cannot thank you enough for saving me from tossing my computer out of the window when I got too frustrated with silly syntax errors in LaTeX. Your support during the writing-up was incredibly helpful and kept me sane.
I want to thank Rohan Raval for always keeping me motivated and cheering me up when I got frustrated. Your help with R was much appreciated.
I thank all the members of the Archaeogenetics group and the Evolutionary Genetics groups for all the constructive discussions during our meetings: Marisa, Bernardo, Ginés, Jade, Alessandro, Marina, Bobby, Gonzalo, Rita, Simão and Pierre.
Giorgia Giordani, Fabiola Tuccia and Jennifer Pradelli, I cannot thank you enough for all your support! I will forever be grateful for your friendship.
I thank Joseph Mwamba Mwansa for being there throughout the biggest stress, for always supporting me and pushing me to be the best I can be.
Last but not least, I would like to thank my family. Without your support I would not be who I am today.

Chapter 1

Introduction

1.1 Human population genetics

The study of the genetic composition of biological populations and their variation is called population genetics. The founders of the field in the 1920s and 1930s were Fisher, Haldane and Wright (Wright, 1949), who developed the first formal models to explore how evolutionary forces impact the genetic composition of a population (Okasha, 2016; Charlesworth et al., 2017). The first studies on population genetics used quantitative traits, such as large chromosomal polymorphisms (Brncic, 1956) and phenotypic serological variation (Cavalli-Sforza et al., 1967), enabling the assessment of the relationships between different human populations. Since the first studies, using "classical" markers such as blood groups rather than molecular markers, Cavalli-Sforza and his colleagues dominated the field of human population genetics (Cavalli-Sforza et al., 1967). The development of Sanger sequencing lifted the field to a new level by allowing direct analysis of DNA variation (Sanger et al., 1977), whilst the invention of the polymerase chain reaction (PCR) (Mullis et al., 1986), which allows amplification of specific small regions of the genome, plus the automation of Sanger sequencing (Smith et al., 1986) further aided analysis. This improvement of sequencing techniques facilitated detailed molecular studies of uniparental markers, such as mitochondrial deoxyribonucleic acid (mtDNA) and the male-specific part of the Y-chromosome (MSY). However, the expense of sequencing multiple genomic loci remained high, and was a major limiting factor for the analysis of larger genomic regions until the recent development of next-generation sequencing techniques (NGS) (Ansorge, 2009; Scholz et al., 2012). Next-generation sequencing has led to the possibility of undertaking large-scale whole-mtDNA sequencing and the generation of complete human genomes. The sequencing of the first whole human genome, the Human Genome Project (Sawicki et al., 1993), began in the 1990s using Sanger sequencing, and the results of this

incredible effort were presented in 2001 (International Human Genome Sequencing Consortium, 2001; Venter et al., 2001) and completed in 2004. Since the development of NGS techniques, several projects have aimed to map human genome variation on a large scale, such as the Human Genome Diversity Project (HGDP), which started in the 1990s (Weiss et al., 1992), the 1,000 Genome Project (Siva, 2008; 1000 Genomes Project Consortium, 2010), and the more recent genome diversity projects of the British Isles: UK10K (The UK10K Consortium, 2015) and the sequel study UK100K, which is currently on-going. While the HGDP and the 1,000 Genomes Project were aiming to map the genetic variation across human populations worldwide, the UK10K project focused on the identification of rare genetic variation through whole genome sequencing of 10,000 genomes from the population of the United Kingdom (UK) (The UK10K Consortium, 2015). After the success of this project, a follow-up study was started by Genomics England, which is currently sequencing 100,000 more British genomes.

The analysis of human history using molecular genetic analysis was defined by Renfrew (2000) as "archaeogenetics". One of the major questions in this subject has been the spread of the Neolithic from the Near East into Europe and its impact on the European population. The focus has since expanded to include most other periods of human history, such as the first arrival of modern humans into Europe and Asia, diversity in early hunter-gatherer populations, the impact of climate change at the end of the ice age, human dispersals out of Ice Age refugia, Bronze Age migrations of the Bell Beaker culture, Roman and Viking invasions, to fine-scale population structure analysis (e.g. Richards et al. 2000; Helgason et al. 2001; Weale et al. 2002; Capelli et al. 2003; Goodacre et al. 2005; Pala et al. 2012; Leslie et al. 2015; Gandini et al. 2016; Gilbert et al. 2017a; Gilbert et al. 2017b). The discipline of archaeogenetics has widely attempted to map the demographic history of the British Isles, but, until recently, with the publication of the People of the British Isles (PoBI) study (Leslie et al., 2015) (discussed in more detail in Appendix B), and a very similar study using the same approach to investigate the fine-scale population structure of Ireland (Gilbert et al., 2017a; Gilbert et al., 2017b), no clear results were available (as summarised in Silva et al. 2019).

1.2 Phylogeography

Phylogeography is a highly integrative approach combining information from population genetics, biogeography, molecular evolution and phylogenetics

in order to describe distributions of genetic lineages across a specific geographic area of interest (Avise et al., 1987). The phylogeographic patterns identified can be used to infer demographic, evolutionary and biogeographic processes (Arbogast, 2001). Mitochondrial DNA diversity has been used to determine phylogenetic relationships among lineages, which can then be further analysed for their geographical distribution and time depth. The combination of phylogenetics with the geographic distribution of genetic lineages can illuminate the divergence and migration history of the species of interest (Hewitt, 2001). A phylogeographic analysis of the British Isles and Europe based on whole mitochondrial genomes can be found in Appendix B and C, respectively.

1.3 Uniparental markers

Uniparental markers, such as mitochondrial DNA (mtDNA) and the Y-chromosome, are used to analyse phylogeographic patterns within species.

1.3.1 Mitochondrial DNA

The human mitochondrial genome is circular, double-stranded and 16,568 base pairs (bp) long. It occurs in multiple, identical copies per cell and the genetic structure is highly conserved (Taanman, 1999). MtDNA is inherited through the maternal line of descent, without recombination, and naturally accumulates mutations over time. This mutation rate can be determined and used to calculate the "mitochondrial molecular clock", which allows for calculations of the ages of different genetic lineages (Soares et al., 2009). This time-dependent mutation rate takes into account the effect of purifying selection on more recent nodes of the complete human mitochondrial tree (Soares et al., 2009). A set of linked alleles, or single nucleotide polymorphisms (SNPs), is called a haplotype, and a cluster of haplotypes sharing a single common ancestor and defined by one or more base variants or SNPs is classified as a haplogroup. The first human mitochondrial genome sequenced (Anderson et al., 1981) was mainly of an individual from the United Kingdom. After re-sequencing, it was revised (Andrews et al., 1999) and this corrected version, known as the rCRS (revised Cambridge Reference Sequence; GenBank: NC_012920), is nowadays used as the reference sequence for mitochondrial genome studies.

1.3.2 Y-chromosome

The male counterpart to mtDNA is the Y chromosome, which is used to trace the paternal line of descent. More than 95% of the Y-chromosome is male-specific, with a total length of ∼58 million base pairs (bp) (Skaletsky et al., 2003). Unlike other chromosomes, the Y-chromosome largely escapes recombination and is usually passed on intact from generation to generation, only changing by mutation (Jobling et al., 2003). As SNPs have low mutation rates, they can provide an extremely detailed phylogenetic tree of Y-chromosomal lineages, and can thus be used to construct unique phylogenies based on the same classification of haplotypes and haplogroups as mitochondrial DNA. Local differentiation of the Y-chromosome can be enhanced as a consequence of patrilocality (Jobling et al., 2003; McEvoy et al., 2008; Gilbert et al., 2017a; Gilbert et al., 2017b).

1.4 Ancient DNA

Genetic population history was, for many years, reconstructed using primarily modern day genetic variation, with, in the case of mitochondrial genomes and Y-chromosomes, estimates of differences through time being calculated through the use of molecular clocks. Archaeogenetic analysis based on this approach, for example using founder analysis to estimate arrival times of populations in a gene pool, dominated the field for several years (see Richards et al. 2008). However, with the advance of NGS techniques, and ever-improving methods in the field of ancient DNA (aDNA), a new dimension has been added to the reconstruction of population history. We can now directly analyse the genetic diversity at specific points in time and space (Hofreiter et al., 2001).

With the possibility of extracting endogenous DNA from ancient tissues of a variety of remains, the field of palaeogenetics emerged. Svante Pääbo pioneered this field for ancient human DNA following the successful amplification of quagga DNA by Higuchi et al. (1984). Since then, studies using aDNA to reconstruct past genomes and facilitate interpretations of the human past have increased exponentially (Rizzi et al., 2012). In 2018 alone (up to September 2018), 772 new whole human genome sequences were published, as well as 102 complete mitogenomes of ancient individuals (Brace et al., 2018; de Barros Damgaard et al., 2018; Mathieson et al., 2018; Mittnik et al., 2018; Neparaczki et al., 2018; Olalde et al., 2018; Valdiosera et al.,

2018), giving incredible new insights into the human past. To date, the oldest sample of successfully amplified and verified aDNA is from a horse found in permafrost dating to 780-560 thousand years before present (kyr BP) (Orlando et al., 2013). This sample likely represents the maximum age range of retrievable ancient DNA. Most ancient sequences analysed date to the Palaeolithic and younger.
Nevertheless, there are several provisos on the use of aDNA, with preservation being the major problem. Bones have been deposited in various ways in different environments, and are thus exposed to varied environmental factors (Winther Pedersen et al., 2015). DNA degradation can be caused by bacterial and fungal DNases, UV radiation, heat, and chemical modifications, such as oxidation, deamination, depurination and other hydrolytic processes (Hofreiter et al., 2001; Willerslev et al., 2005; Winther Pedersen et al., 2015), leading to highly fragmented and modified DNA. One of the best environments for aDNA preservation is permafrost (Hofreiter et al., 2001; Willerslev et al., 2005; Winther Pedersen et al., 2015) due to the stable low temperature. Generally, the survival of aDNA in temperate climates can also be good, and there are several outstanding publications reporting complete and partial ancient genomes of hominins, animals and plants (for example Krings et al. 1997; Pääbo et al. 2004; Coolen et al. 2006; Noonan et al. 2006; Orlando et al. 2006; Gamba et al. 2014; Epp et al. 2015; Günther et al. 2015; Lazaridis et al. 2016). The most problematic depositional areas are wet and warm climates, because these conditions facilitate fast DNA degradation. Another problem is the geographic distribution and availability of ancient samples. Concerning human remains, different burial rituals can also skew the reconstruction of ancient populations due to stochastic inhumation and preservation.

1.4.1 Ancient DNA from bones and teeth

Because they are often the only physical remains surviving, bones are the main source of DNA information from human and other animals. Bone degradation has been well studied in the decades since the discovery that proteins and DNA survive in ancient tissue (Tuross, 1994; Collins et al., 2002). The basic building block of bone is the mineralised collagen fibril, which, together with bone vascularisation, determines the bone microstructure through its organisation (Collins et al., 2002; Mrevlishvili et al., 2005). The bone matrix consists of several highly mineralised discontinuity layers, called cementing lines (Campos et al., 2012), which are the separating anatomical units. Bone

is composed of hydroxyapatite (HAP) and organic material, such as collagen, osteocalcin and osteonectin (Campos et al., 2012). Collagen promotes the stabilisation of the DNA double helix and its hydration shell through hydrogen bond formation (Mrevlishvili et al., 2005), which might also prolong DNA survival (Campos et al., 2012). After death, hydrolysis starts to degrade the collagen, leaving the DNA unprotected (Collins et al., 2002), with the DNA surviving in the bioapatite crystals in the bone structure (Campos et al., 2012). This highlights that the inorganic component of bone is at least as important for the long-term survival of DNA as the organic component, with DNA being trapped in the osteoid as it forms (Collins et al., 2002; Campos et al., 2012). Four possible locations for DNA survival in bones have been postulated, which can be separated into two forms of preservation: *in vivo* (where DNA is overlain or encapsulated by HAP) and post-mortem (where DNA is released from collagen fibrils into the macroporosity of the bone during degradation or trapped by HAP during bone mineral re-crystallisation) (Campos et al., 2012). Considering the role of bone apatite for DNA preservation, a stable, slightly alkaline pH in the environment makes limestone caves a very good source for aDNA, especially as they also have an almost constant cold temperature (Collins et al., 2002; Edwards, 2012). The key mechanism for the fossilisation of bones is the slow loss of collagen by chemical hydrolysis, coupled with infilling of subsequent porosity (Collins et al., 2002). This is dependent on time, temperature and the pH of the environment, but mainly on the hydrology of the site, as mineral transformations will expose collagen to an accelerated chemical and biological degradation (Collins et al., 2002). The most common mechanism is the degradation caused by microbial activity (biodegradation), which is optimised at near-neutral pH conditions that otherwise protect the bone (Collins et al., 2002). In general, the survival of DNA in bone is strongly dependent on the differences in burial rituals and burial environments.

As well as bone, teeth can be used for DNA studies. They have a comparable preservation to that seen in the petrous bone (Hansen et al., 2017), discussed below. The tough enamel and cementum of whole teeth, or tooth roots embedded in the mandibular or maxillary bone, can provide improved protection for DNA in many environments and, additionally, DNA appears less prone to contamination from modern DNA (Adler et al., 2011).

1.4.2 Petrous bone

Several different bone elements have been tested for endogenous DNA retrieval. In general, harder, denser bone preserves endogenous DNA better (Haynes et al., 2002). The hardest bones in the human body are found in the skull. The average success rate of DNA recovery of various cranial bones varies between 52-68% for the parietal bone, occipital bone and the frontal bone (Pinhasi et al., 2015). The hardest and densest bone part is the temporal bone, which is located at the base of the skull between the sphenoid and occipital bones (Gamba et al., 2014; Pinhasi et al., 2015). The petrous part of the temporal bone comprises the otic capsule (bony labyrinth) of the inner ear (see Figure 1.1 A and B red square), and the inner petrous portion of the temporal bone has allowed extraction of endogenous DNA of up to 90% (Pinhasi et al., 2015). Since the density throughout the petrous bone is not uniform, the endogenous DNA content of different sections has been tested (Pinhasi et al., 2015); with the densest bone parts within the otic capsule providing the highest endogenous aDNA yields (Pinhasi et al., 2015).

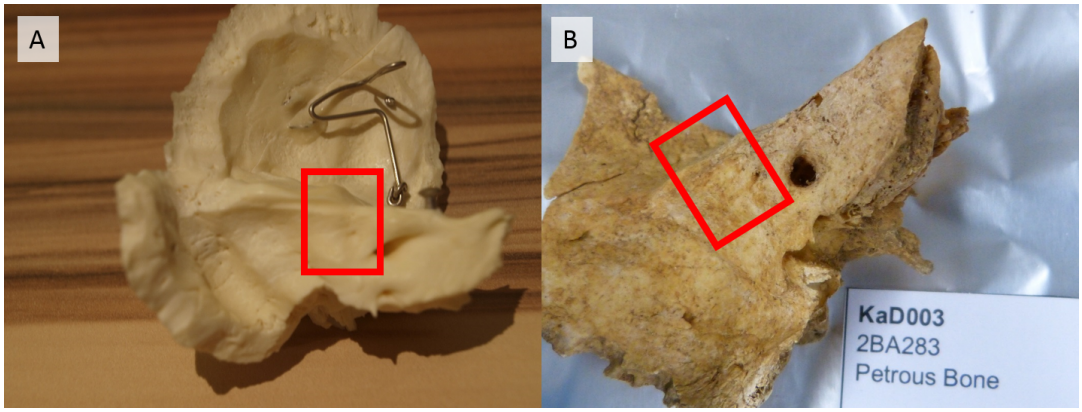

FIGURE 1.1: The petrous part of the temporal bone. A - a modern left petrous bone; B - an ancient left petrous bone. The red square indicates the position of the inner petrous portion, comprising of the otic capsule.

It has been shown that petrous bones from warmer regions of the world can contain surviving DNA, allowing analyses of samples from hot environments (Pinhasi et al., 2015). A more recent study compared the preservation of DNA in the petrous bone with that of tooth cementum, with the petrous bone generally containing higher endogenous DNA yields (Hansen et al., 2017), showing that both substrates are excellent for ancient genomic research.

1.5 Dietary stable isotopes

The analysis of carbon and nitrogen stable isotopes for dietary reconstruction is commonly undertaken on dentine or bone collagen. As collagen is mostly directly synthesised from dietary protein, its isotopic composition thus reflects the main protein source. Due to the different turnover times of collagen in different types of bones, different bones reflect the diet of an individual at different life stages (Chenery et al., 2010). During childhood, the dietary isotopic signature at the time of tooth formation is preserved in the dentine, whereas dietary isotopic signatures of an individual's adulthood are preserved within the growth of long bones during adolescence and following decades (Chenery et al., 2010). Dietary reconstruction uses carbon stable isotope ratios ($\delta^{13}C$) to distinguish between major food sources, such as C3 and C4 plants, and the products of animals feeding on these plants (Chenery et al., 2010). In temperate climates, they are mainly used as differentiation between marine food and terrestrial C3 plant-based foods. Nitrogen stable isotope ratios ($\delta^{15}N$) are used to complement $\delta^{13}C$, as they give an indication of the trophic level an organism is feeding at, which allows an estimation of the importance of animal and plant-based foods in an organism's diet (Chenery et al., 2010). The reconstruction of diets of ancient populations using carbon and nitrogen stable isotope analysis has illustrated significant differences in diet across populations (Schulting et al., 2002a; Evans et al., 2006; Müldner et al., 2007; Chenery et al., 2010).

1.6 The peopling of Britain

1.6.1 First modern humans

The settlement history of the British Isles is full of unanswered questions. Although the first modern human remains date to before the Last Glacial Maximum (LGM), ~26.5-19.5 kya (Barton, 1999), little is known regarding migration, admixture and continuous occupation of Britain during the Pleistocene and subsequent Holocene. During this time, with the relatively isolated peripheral position of the islands, facing the Atlantic at one edge of the European peninsula, the British Isles were only accessible by sea and primarily from one direction, namely the European mainland (France, Belgium, Netherlands, Germany, Denmark). It is likely that *Homo sapiens* in Britain disappeared by ~24,000 years BP, driven out by the climatic conditions of the

LGM.
The earliest dated modern human remains in the British Isles are from Goat's Hole Cave, Paviland, in Wales. Part of a ceremonial burial, and erroneously originally entitled the "Red Lady", the skeleton was of a young adult male, dating to the Early Upper Palaeolithic ($25,840 \pm 280$ cal. BP; OxA-8025) (Aldhouse-Green et al., 1998). The individual had been buried with a handaxe, discoidal cores, leaf points and carinated scrapers, making this by far the richest Aurignacian site in Britain (Aldhouse-Green et al., 1998; Dinnis, 2012). The population to whom the "Red Lady" belonged colonised Britain in the Early Upper Palaeolithic, but then most likely moved south in front of the extending ice caps (Figure 1.2),(Aldhouse-Green et al., 1998). Populations substantially declined and only temporary (possibly seasonally) occupied northern Europe during the LGM, rapidly expanding into northern areas as soon as the temperatures increased (Blockley et al., 2006).
The onset of warmer conditions after ∼13,000 BP (Windermere Interstadial) facilitated the earliest reappearance of hunter-gatherers in the British Isles (Housley et al., 1997). Human remains from this period are extremely rare, especially ones with associated radiocarbon dates. With radiocarbon ages of *ca*. 12,600 cal. BP, Gough's Cave and Sun Hole (Cheddar Gorge, Somerset), Aveline's Hole (Mendip, Somerset) and Pixie's Hole (Chudleigh Valley, Devon) have the oldest Late Glacial determinations of human presence in the British Isles (Jacobi et al., 2009). During this period the Creswellian culture (the British Late Magdalenian) emerged and most human activity was preserved in the form of modifications and cut marks on bones, worked antler and ivory (Barton, 1999), as well as stone blades and bladelets (Wygal et al., 2014). By the time of the Younger Dryas (∼12,900-11,700 BP), the climate had once again returned to much colder conditions, and there is no reliable evidence of human activities from this period, possibly because populations were driven out of Britain due to the cold (Barton et al., 2003; Cunliffe, 2013). It is as yet unclear if occupation of the British Isles continued throughout the Younger Dryas or not.

1.6.2 Mesolithic

Only at the end of the Younger Dryas can more confidence be attributed to the presence of humans in the British Isles. Star Carr, the "type site" for the British Mesolithic, has been been argued to have been a specialised site for the working of antlers (Mithen, 1999). Radiocarbon dating places the occupation of this Mesolithic site to $10,920 \pm 80$ cal. BP and $10,740 \pm 130$

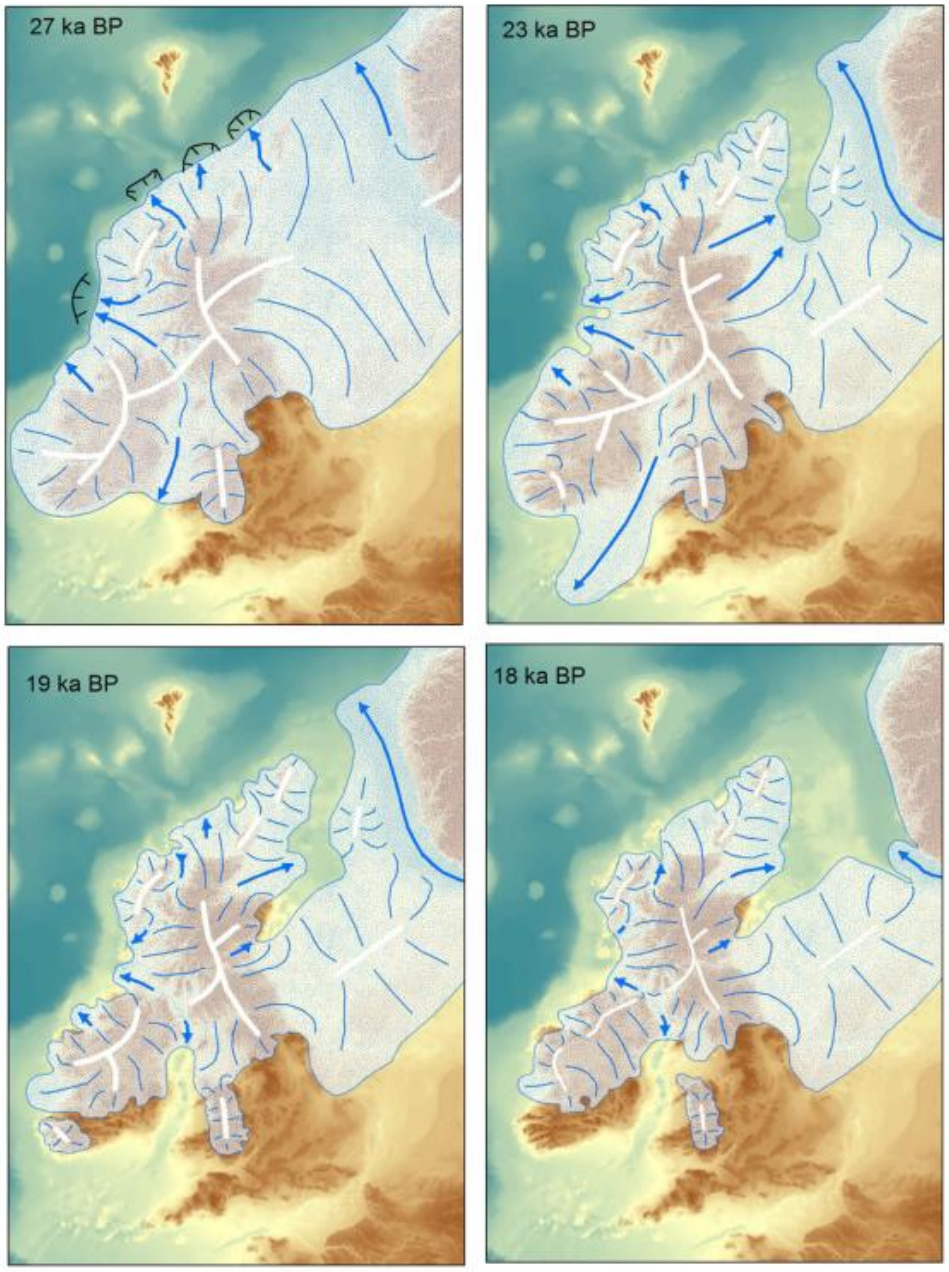

FIGURE 1.2: Ice cover Britain. Location of ice sheets in the British Isles at different time periods (adapted from Clark et al. 2012).

cal. BP (Dark, 2000). Other Early Mesolithic sites in Britain are: Thatcham in Berkshire, occupied between $10,365 \pm 170$ cal. BP and $9,480 \pm 160$ cal. BP; Oakhanger in Hampshire, occupied around $9,045 \pm 66$ cal. BP (Mithen, 1999); and a site in Northamptonshire, which was dated to $10,320 \pm 150$ cal. BP (OxA-803) based on a worked reindeer antler object (Cook et al., 1994).
During the Mesolithic, around 8,500 BP, the British peninsula became an island (White et al., 2000). The melting ice sheets caused extreme changes in the northern landscapes of Britain, and increasing temperatures supported a

rapid change in fauna and flora of the emerging island. The amount of charcoal finds increases at this period, as hunter-gatherer populations started to modify their surrounding landscapes by intensifying wild plant husbandry, forest clearances and vegetation disturbance, which was mainly accomplished by burning and ring-barking (Brown, 1997). The hunter-gatherer lifestyle continued until the onset of the Neolithic in the British Isles, ∼6,200 years ago.
Similarly to the Palaeolithic, human bones are extremely rare finds in this period. However, recently, the genome of an individual found in Gough's Cave, Somerset, named "Cheddar Man", was analysed, along with five other Mesolithic individuals from Britain (Brace et al., 2018). Interestingly, all of these people had genetic similarity to western hunter-gatherers (WHG) in Europe, such as from Loschbour in Luxembourg (Brace et al., 2018), and Cheddar Man himself was predicted to have had dark hair and a dark skin colour.

1.6.3 Neolithic

The first domestication of cereal crops and sheep, goats and pigs took place around ∼9,000 BC (11,000 BP) in the Near East (Ammerman et al., 1984). Along with this Neolithic transition, several cultures arose between 8,000-4,000 BC as people moved across Europe, spreading agriculture and introducing new patterns of settlement (Haak et al., 2010). The spread of the Neolithic was either based on the migration of people or on the adoption and spread of ideas. The traditional model, put forward by Cavalli-Sforza and his colleagues in the 1980s, suggested a large influx of people from the Near East at the start of the Neolithic and a rolling wave of advance of Near Eastern farmers across Europe, with continuous admixture at the wave-front (Ammerman et al., 1984). By contrast, mitochondrial studies in the 1990s proposed a smaller-scale pioneer colonisation for the earliest farmers in Europe and emphasised an important role for the later, gradual assimilation of indigenous hunter-gatherer lineages in the ancestry of European populations (Richards et al., 2000), whereas more recent ancient DNA studies have uncovered a discontinuity of mtDNA (Haak et al., 2005; Haak et al., 2010; Brandt et al., 2013; Deguilloux et al., 2012) and Y-chromosome (Lacan et al., 2011a; Lacan et al., 2011b; Lacan et al., 2013) lineages between Mesolithic hunter-gatherers and Neolithic farmers. The most common Y-chromosome haplogroup in western Europe is R1b, which was initially dated to have originated in the Paleolithic (Semino et al., 2000) in Iberia, but has since been

shown using aDNA to have arisen in the east, probably Ukraine/Russia, and expanded to the west into Iberia (Brandt et al., 2015).
Genome-wide studies have found three main components of autosomal genetic ancestry in Europeans. Firstly, what can be termed a "western hunter-gatherer" component, seen in the present day Saami population (who lack Neolithic ancestry), but at very low level in modern Near Eastern people (Pereira et al., 2017). A second "Neolithic" component, common today across the Near East and Mediterranean Europe, was carried by Early Neolithic individuals in these regions, as well as in Iberia. The highest levels of this Neolithic ancestry are found in modern Sardinians (>50%) (Keller et al., 2012; Sikora et al., 2014), Neolithic Anatolians ($\sim$90%) and Neolithic and Epipalaeolithic Levantine populations ($\sim$100%) (Lazaridis et al., 2016). These observations suggest the arrival of pioneer-colonists with a new genetic make-up into Europe during the Early Neolithic. The third ancestry component, the "Steppe" or "Caucasus hunter-gatherer" component, spread from the east into Europe during the Late Neolithic/Bronze Age, and originated in the Mesolithic of the Iran/Caucasus region (Jones et al., 2015; Lazaridis et al., 2016). These population movements and admixture considerably reshaped the gene pool of western Eurasia within the past 5 kya (Allentoft et al., 2015; Haak et al., 2015).
The location of the British Isles at the western outskirts of Europe delayed the arrival of the Neolithic transition compared to most other European countries, and the environmental conditions were generally more demanding for the practice of farming (Ammerman et al., 1984). The transition from hunting and gathering to farming had a strong impact on the transformation of the landscape, due to deforestation, land clearances for agricultural use, and burning (Woodbridge et al., 2014), and was extremely disruptive (Rowley-Conwy, 2004). Thus, the earliest agricultural activity in Britain is thought to date back to *c.* 4,000 BC or slightly earlier (Woodbridge et al., 2014). Conflicting scenarios for the spread of the Neolithic in Britain have been proposed. The first appearance of Neolithic activities around 4,100 cal. BC spread from the south-east to the north-west as a gradual and regional phenomenon, until it also became established in Ireland and Scotland by around 3,800 cal. BC (Whittle et al., 2011). Alternatively, it has also been postulated that the introduction of the Neolithic may have arisen through several migrations, deriving from different regions across the north of France (Sheridan, 2010).
Some of the emerging Neolithic cultures created distinct forms of pottery,

where the pottery styles found in Britain differ from the ones found in Germany and Denmark (Ammerman et al., 1984). Furthermore, distinct geographic traditions existed across the British Isles alongside a "standard" package of codes and practices as associated with the Neolithic package (Harding, 1997). Significant contrasts between North Yorkshire and lowland England are visible in geographic differences and monuments, as well as differences between Early and Late Neolithic enclosures (Harding, 1997). Neolithic settlements in Scotland had their own local pottery variations (Cowie, 1993).
An innate character of Neolithic societies was the large aggregation of people per site and the gradual development of individual burials and causewayed enclosures, which set the basis for a long-term continuity of social histories within different regions (Harding, 1997). The spread of Neolithic activities in Britain differs from the European mainland, and the genetic admixture during the colonisation phase differs from that seen in other European regions at the same time (Brace et al., 2018). Whereas in mainland Europe, where the colonisation by farmers from the east took place much earlier, slow admixture processes occurred in local populations (Brace et al., 2018). By contrast, there is overwhelming support for agriculture being introduced into Britain by incoming continental farmers, with only small and geographically structured levels of introgression from the indigenous hunter-gatherer populations. Across Britain, the evidence for admixture between hunter-gatherers and farmers is limited, with early British Neolithic farmers deriving two-third to three-quarters of their ancestry from Anatolian farmers, with similar ancestry proportions as found in the Early Neolithic in Iberian and Middle Neolithic central European individuals (Brace et al., 2018). Neolithic individuals from Wales exhibited the lowest levels of western hunter-gatherer ancestry, whilst south-east England and Scotland retained the highest western hunter-gatherer ancestral proportions (Brace et al., 2018). The substantial descent of British farmers from populations related to the Iberian Neolithic indicates that immigration of farmers from the European continent was the major factor for the appearance of the Neolithic in Britain and that the immigration was primarily from Iberia (Brace et al., 2018; Olalde et al., 2018).
Our understanding of ancient people increases in the Neolithic. This is based on the increasing number of burial sites and the growing and spreading populations at this time. The large number of archaeological finds from this period are due to the adoption of a more sedentary lifestyle and the development of new settlements and social cultures, including burial rites, which increases the possibility to study local relationships and status of people.

1.6.4 Bronze Age

The Bronze Age in the British Isles (2,500-800 BC) is identified first by the use of copper, and then bronze as a technological innovation, and both were associated with societal changes. The first evidence of copper metallurgy in the British Isles is from 2,400 BC in Ireland, with other mines established around 1,900 BC in parts of northern England and Wales (Bradley, 2007). The Bronze Age is a crucial period in the development of the British Isles, due to the changes in settlement, burial rites, pottery styles and building of monuments (Parker Pearson, 1999). Settlements enclosed by ditches and palisades appeared, as well as wheeled vehicles and evidence of thriving sea-borne trade (Champion, 1999). At the beginning of the period, people began to be buried individually but, during the Middle Bronze Age, cremation became universal and grave goods were largely limited to Deverel-Rimbury pots that contained the ashes. Pottery is the key artefact of this period as, along with burial rites, it was used in daily routine and food preparation, as well as a means of social identity (Champion, 1999). In the later Bronze Age (from $\sim$1,400 BC), people started dividing the landscape into a pattern of territories, containing access to valley land, upland and access to open moor (Champion, 1999). By $\sim$1,000 BC many of these territories had been partially abandoned, possibly due to climatic deterioration or human over-exploitation (or both) (Champion, 1999). By the end of the Bronze Age, both Ireland and Britain sustained contacts with continental Europe (Mallory, 2013). The culture with possibly the biggest impact on western Europe at this time was the Bell Beaker culture that originated in Iberia and spread into central and north-western Europe between 2,750 and 2,500 BC (Kristiansen, 2014; Brandt et al., 2015; Olalde et al., 2018). With the rise of the Bell Beakers, a network of trade and migration was installed across Europe, circulating metal goods within Ireland and Britain and beyond, and also leading to immigration from northern Britain and the Atlantic fringe to Ireland, and *vice versa* (Mallory, 2013).

Strontium and oxygen isotope analysis of British Bell Beaker remains have shown that these people must have travelled some fair distance in their lifetime. One such example is the Amesbury Archer, who was buried near Stonehenge around 2,300 BC. He is associated with the earliest Bell Beaker phase in Britain and was accompanied by a rich amount of grave goods. According to stable isotopic analysis, he may have been a long-distance traveller from the Rhine (Pearson et al., 2016). However, long-distance travel, such as this individual may have undertaken, is considered an exception. Although

analysis of >250 Bell Beaker individuals from across Britain indicated a considerable degree of mobility between their childhood and death, mostly only moved around within Britain (Pearson et al., 2016).
A recent large-scale whole-genome analysis of 400 European individuals from the Neolithic, Copper Age and Bronze Age, of which 226 were associated with the Bell Beaker culture, documents a phenomenon of almost complete population replacement in Britain with the arrival and spread of the Bell Beakers (Olalde et al., 2018). About 90% of the British gene pool was replaced within a few hundred years. British Neolithic individuals were clearly distinct from the British Beaker-associated people, as the latter brought large amounts of Steppe-ancestry into the country (Olalde et al., 2018). This study showed that the Steppe-ancestry arrived earlier into Britain (∼2,500 BC) than into Ireland (∼2,000 BC) (Cassidy et al., 2016), and that this genetic component is still predominant in the modern British population (Olalde et al., 2018). Beaker individuals from southern Britain showed closest genetic affinity to Bell Beaker individuals from the Netherlands (Olalde et al., 2018). Their level of shared genetic drift, and identical levels of Steppe-related ancestry, suggest that they likely share the same ancestral gene pool (Olalde et al., 2018). Y-chromosome haplogroup R1b represents over 90% of the sequenced British Beaker and Bronze Age men, while, so far, no British Neolithic individual belonging to this Y-chromosome haplogroup has been found (Olalde et al., 2018). The maternal lineage compositions of the indigenous Neolithic people and that of the arriving Beaker-associated individuals suggest that this movement involved both men and women, because the mtDNA haplogroups were introduced at the same time as Y-chromosome haplogroup R1b (Olalde et al., 2018), although the mtDNAs so far identified as new arrivals are a small minority, so it appears that there was a sex bias in the movement of people into Britain.

1.6.5 Iron Age

Iron-working began in Britain ∼800/700 BC. Pastoral farming was expanded and hillforts, such as Cadbury Castle (Somerset), Croft Ambrey (Herefordshire), Danebury (Hampshire) and Maiden Castle (Dorset) (Haselgrove, 1999), were increasingly used. After ∼350 BC, the majority of the hillforts were abandoned, while a smaller number were massively elaborated and heavily protected (Haselgrove, 1999). Cult centres developed and wares were exchanged over wide distances, which brought the British Isles into contact

with the Roman Empire. The increase in the number of settlements at this time has been interpreted as a sign for rising population numbers (Haselgrove, 1999), and the trading network throughout Europe was in constant use, bringing even exotic presents, such as the Barbary ape, into Ireland (Newman, 1998). The large town-like settlements of the Iron Age allowed people to change their social networks to smaller, more flexible ones compared to the strong bonds of country life (Pryor, 2004). The lack of burials, due to cremation and excarnation of the dead, has had a strong impact on the survival of Iron Age material culture.
The Arras culture, found in East Yorkshire but uncommon elsewhere in Britain (Hill, 1995), was loosely associated with the Parisi tribe of pre-Roman Britain (Dent, 1983), and similar to the La Téne culture found in continental Europe. They were defined by the peculiar burials of local elite in disassembled chariots and square enclosures, accompanied by high quality metalwork, which is often unique in Iron Age Britain, as well as the use of imported materials in the grave goods. The skeletons were placed in a north-south orientation, with the head facing north, and pig and horse bones were frequently buried alongside. Genetic analysis of Late Iron Age individuals from southern England has shown that these individuals shared ancestors with multiple northern European populations, such as England, Denmark, Finland and the Netherlands (Schiffels et al., 2016).

1.6.6 Roman conquest

The main landscape change during the Roman period in Britain was the building of roads and towns, which still influence the landscape today, and timber for building was replaced by stone during the Iron Age/Roman overlap (Pryor, 2004). Southern Britain was already in regular contact with the Roman Empire during the later Iron Age (Mallory, 2013), although Roman contact with Scotland, which had been largely unconquered, and Ireland, was less established. Even more so than during the Bronze and Iron Ages, people moved around during this time , as being incorporated into the Roman Empire, ranging from Europe, over North Africa to the Near East, resulted in movement, both voluntary and forced (Leach et al., 2010). Trade was also a significant part of daily life, with Britain providing slaves and raw-materials to the Empire in exchange for high-status commodities, such as wine (Pryor, 2004). The population structure was quite diverse, with a strong Roman impact in south-east Britain compared to the rest of the British

Isles (Pryor, 2004). The large proportion of Roman soldiers of Germanic origin by the late 4th century AD, and the hire of free mercenaries to support the Roman army during the 5th century AD, were reflected in the diversity of the British population during this period (Pryor, 2004). Not only a range of European people, but also individuals of varying status from further abroad, made it to Britain (Leach et al., 2010), leading to the possiblity of further admixture.

The Roman influence on Scotland was limited to the south, which was later manifested through the building of Hadrian's Wall and the Antonine Wall (Breeze et al., 1976). These restricted movements between the north and south of Britain has influenced the diversity and admixture of modern-day populations. Romano-British genomes from a cemetery in York showed a significant divergence from modern Yorkshire and eastern English individuals, whilst they showed particular affinity to the modern Welsh population (Martiniano et al., 2016). When compared to earlier Iron Age samples from East Yorkshire, there appeared to be continuity in the area. However, the Roman genomes differed from Anglo-Saxon genomes from the same region (Martiniano et al., 2016), suggesting a population continuity before the Anglo-Saxon migrations into Britain.

1.6.7 Anglo-Saxon Britain

The Romano-British and Anglo-Saxon periods in Britain were very different, separated by ethnicity, culture and religion. Despite this, in some places there was little or no break in the field system and settlement patterns, and Romano-British fields were subsequently used by the incoming Anglo-Saxons (Pryor, 2004). The withdrawal of the Roman legions from the British Isles led to a decrease in population (Pryor, 2004), and the main question concerning the Anglo-Saxon arrivals in Britain is: what happened to the indigenous people?

In order to try and answer this question of population replacement or admixture, several studies used modern Y-chromosome DNA data, and between 25 and 100% contribution to the modern male English gene pool was estimated (Weale et al., 2002; Capelli et al., 2003; Thomas et al., 2006). The overlay of subsequent migrations on any original Anglo-Saxon introgression renders this approach problematic, especially when incursions from Danish populations are considered, as their male gene pool is basically identical to the Anglo-Saxon one (Capelli et al., 2003). This is due to both low resolution of the genetic markers and poorly defined and overlapping source regions.

Future high resolution studies will likely be able to show differences, and a whole genome approach would greatly benefit any conclusions.
In 2002, Weale et al. suggested, based on an east-west transect of modern-day Britain, that an Anglo-Saxon mass migration, with an associated Y-chromosome gene flow, occurred into central England, but not into Wales.The first detailed dataset of modern British Y-chromosome variation, using low-resolution microsatellites and a small number of haplogroup-defining SNPs, was built up by Capelli et al. in 2003. They saw a trend for Wales, Scotland and Ireland to resemble more closely the Basques, and for English regions to be more similar to the European continent, especially to the likely Anglo-Saxon source populations. This finding was more recently confirmed at the genome-wide level by Leslie et al. (2015), and has since further been supported by the analysis of ancient genomes from Yorkshire, which showed that Romano-British and Anglo-Saxon genomes from the same region differ significantly (Martiniano et al., 2016).
In order to explain the higher reproductive success of Anglo-Saxon immigrants, differential status and reproductive isolation among the different ethnic groups have been suggested. A 7th century AD Wessex law code clearly distinguished between Saxons and native Britons, giving the former a higher legal status (Thomas et al., 2006). Limited intermarriage and differences in reproductive success could also be an explanation for the higher contribution to the modern English gene pool of an initially small Anglo-Saxon immigrant population (Thomas et al., 2006). However, analysis of Anglo-Saxon individuals from the early (fifth to sixth century AD) and middle (seventh to ninth century AD) Anglo-Saxon periods at Oakington in Cambridgeshire, England, produced no evidence for segregation of indigenous people and Anglo-Saxon incomers, but rather genetic admixture and identical cultural community (Schiffels et al., 2016). This was reflected in the archaeological record, as genetically indigenous, admixed and foreign individuals were all buried in similar graves, alongside similar grave goods. One of the genetically foreign Anglo-Saxon individuals was the only burial without any grave goods at this site, suggesting that new immigrants may have been less wealthy than locals (Schiffels et al., 2016).

1.6.8 Vikings in Britain

In $\sim$800 AD, Scandinavian raiding parties started to hit vulnerable coastal areas of the British Isles, mainly monasteries (Richards, 1999). These raids started as hit-and-run affairs, but eventually the Vikings settled. The north

of the British Isles (Scotland, Scottish Isles and the Isle of Man) was colonised by the Norse, whilst Anglo-Saxon England was invaded by Danes, with the exception of the extreme south of England. It is unknown when and how the Vikings started to occupy, conquer and colonise the islands (Ó Corráin, 1998), but it is clear that raiding and exploiting areas in the British Isles created destabilisation that preceded the permanent Viking settlements. The establishment of a slave trade among the settlements led to enhanced possibilities for further admixture (Pearson, 2006). For the Anglo-Saxons especially, invasions led to major economic and social change, and the formation of a network of fortified towns, which later developed into medieval towns (Richards, 1999). As these fortified towns were under royal protection and control, they became the centres of trade, industry, minting and taxation.
The settlements of the islands of Orkney, Shetland and the Isle of Man are special cases, since the cultural connections in these areas are nowadays strongest to Scandinavia. The analysis of Y-chromosomal DNA in modern Orkney populations has revealed closer relationships with Norway than with the rest of the British Isles (Wilson et al., 2001). Similar frequency patterns have been observed in other Norse colonies of Iceland and the Faroes (Helgason et al., 2001; Goodacre et al., 2005). Further analyses of both uniparental markers in Scotland have inferred a considerable Norse component (between 15% and 30%) of the maternal lineage, and suggested family-based settlements with roughly equal numbers of Scandinavian female and male migrants (Goodacre et al., 2005). The Earldom of Orkney was the centre of diverse Norse activities in the North Atlantic region and the intensity of these activities is consistent with the different estimates of Scandinavian ancestry for mtDNA lineages in Orkney, the Western Isles, the Isle of Skye and the north-west coast of Scotland (Helgason et al., 2001).

1.6.9 Ireland

Sea levels fell during the Ice Age, and, prior to 16 kya BP, Ireland became accessible from Britain (Figure 1.3) (Clark et al., 2012; Mallory, 2013), making it possible for hunter-gatherers to follow the ice sheets and reach Ireland on foot. It is argued that southern Ireland was even connected to northern France (Woodman, 1986), although this is not very likely. With the discovery of a human-modified brown bear patella in Alice and Gwendoline Cave in Ireland, colonisation of Ireland during the Palaeolithic is now argued to be evident (Dowd et al., 2016), although this patella might have originated elsewhere and been brought to Ireland at a later date.

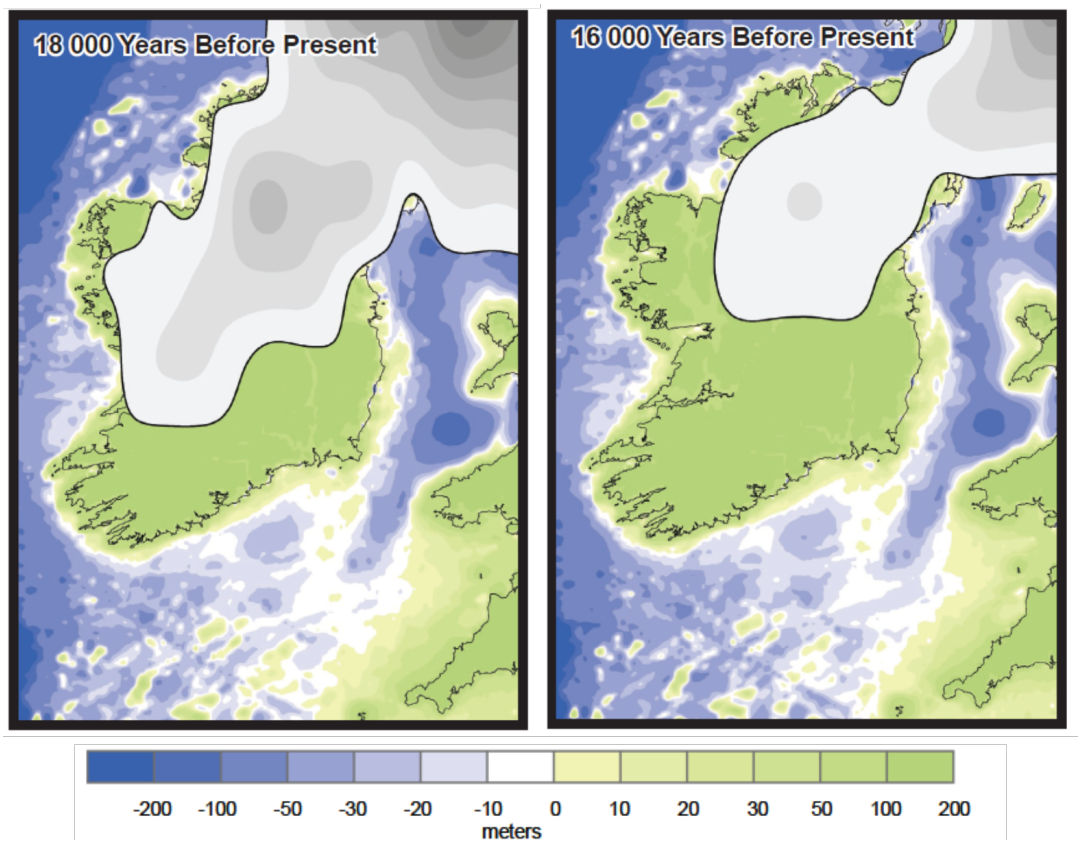

FIGURE 1.3: Map showing the post-LGM landbridges between Britain and Ireland with ice sheets retracting (adapted from Edwards et al. (2008)).

Around 20 kya, ice sheets started retreating and parts of north-eastern and south-western Ireland once more became ice-free (Clark et al., 2012). By 14,000 BP, Ireland was completely ice-free (Edwards et al., 2008), allowing people into Ireland once again. Sea levels rose again with the end of the last Ice Age (∼12,000 BP), making Ireland as the island it is today, and possibly leading to a loss of archaeological coastal sites and their artefacts (Mallory, 2013).

The oldest Mesolithic settlement in Ireland is Mount Sandel, where the remains of huts, stone tools, and assemblages of animal bones showing cut-marks have been discovered (Mallory, 2013). The local elements occurring in the Mount Sandel assemblage differ from any forms found in Britain. The time required for local forms of artefacts to develop suggests that Mount Sandel was occupied some time after an initial phase of settlement in Ireland (Bayliss et al., 2009), and the situation in Ireland does not resemble that of any other area in Europe. Late Mesolithic hunter-gatherer-fisher settlements, such as at Ferriter's Cove, where domesticated cattle remains were found, suggested the possibility of episodes of early contact between Late Mesolithic Irish populations and Mesolithic and/or Neolithic groups from

the continent (Sheridan, 2010). The ceramic and Mesolithic tomb types found in Ireland seem to have a common origin with those found in Britain, yet they are not quite the same (Sheridan, 2010). Passage tombs in Ireland follow a long sequence of development and persist much longer than in most regions of Britain, where they were possibly re-introduced from Ireland at a later stage (Sheridan, 2010).

Bayesian chronologies of plant macro-remains (Rowley-Conwy, 2004; Mallory, 2013; Whitehouse et al., 2014), suggest that the spread of the Neolithic in Ireland must have been extremely rapid, which has been argued to have been facilitated by the use of waterways (Davison et al., 2006). Since any cultural change seen in the archaeological record may have been due to migrations of people into Ireland, the genetic continuity of Irish populations at this time has been a focus for analysis. A Neolithic individual from Northern Ireland was found to have early farmer ancestry similar to other Neolithic individuals from the Atlantic fringe, whose populations originated in the Near East and spread through Europe during the Neolithic (Cassidy et al., 2016). This genome also showed hunter-gatherer introgression, suggesting admixture of ancestral farmers with Mesolithic hunter-gatherers, although it is unknown where this introgression took place. Bronze Age samples from Ireland, like those from Britain, suggested genetic discontinuity, with significant amounts of introgression of an ancestral component from the Steppe, implying that population movements in the Bronze Age, largely attributed in western Europe to the Bell Beaker culture, reached all the way to the north-western edge of Europe into Ireland (Cassidy et al., 2016). However, the sample number from Ireland to date is extremely low (one Neolithic and three Bronze Age individuals, all from the north-east close to Scotland) and so further studies are needed to support this.

While people in Britain increasingly started using iron around 800 AD, there is no extreme shift from bronze to iron in Ireland and, although small-scale movements between Britain and Ireland are suggested based on the comparability of the earliest iron metallurgy and material culture, no evidence for major migrations or population movements into the island currently exist (Mallory, 2013).

The Vikings started to raid Ireland in the late 8th century AD, followed by the establishment of settlements in the early 9th century AD, starting from Norway, but later coming from their established settlements in Scotland (Ó Corráin, 1998). Initially, raids were only seasonal but, over the years, these gave way to the establishment of winter-camps. While most camps were not

occupied for long, a few developed into permanent bases and larger settlements, where trading and other economic functions developed, such as at Dublin and Waterford (Sheehan, 2008). The Viking settlements in Ireland that engaged in international trade became areas of urbanisation, especially in the coastal areas (Doherty, 1980).

A modern genetic investigation of patrilineal kinship structures in Ireland showed no universal feature of Irish tribal units, such as under Ui Neill (McEvoy et al., 2008), while the study by Moore et al. (2006) suggested a strongly influenced social selection of the Y-chromosome. A much more recent divergence of population structure within the Irish population are the Irish travellers (North et al., 2000; Relethford et al., 2013; Gilbert et al., 2017a). After much debate, modern population analysis showed that the travellers are of Irish origin, rather than Roma descendants as originally believed, and that this divergence was not a sudden event, but a rather gradual population development due to separation over time (North et al., 2000), and the genetic differences between Irish travellers and settled Irish populations has been shown to be due to genetic drift rather than external gene flow (Relethford et al., 2013). This most likely occurred due to the potato famine (1845-1849 AD: Woodham-Smith 1962), which caused people to leave their homes, and many varied groups joined the original population of travellers of craftsmen and artisans (Crawford et al., 1974; North et al., 2000). A fine-structure analysis of the modern Irish population, including the Irish travellers, linked individuals with four generations of ancestry to specific regions in Ireland (Gilbert et al., 2017a). Using a fine-structure approach, the Irish population could be divided in 10 distinct geographically stratified genetic clusters, seven of "Gaelic" Irish ancestry and three of shared Irish-British ancestry. The study revealed a major genetic barrier to the north of Ireland in Ulster and a surprising amount of Norwegian-like ancestry (similar to the north and western coasts of Norway) accounting for $\sim$20% of the gene pool. Furthermore, the study suggested a low, constant level of gene flow across Ireland and Scotland prior to Viking admixture. Genetic clusters specific to the Irish traveller population, which reflect sociolinguistic differences, could also be identified, and a high degree of homozygosity and high frequencies of otherwise rare variants were observed in the fine-scale genetic analysis of the Irish traveller population (Gilbert et al., 2017a). Overall, the Irish population is genetically closest to south-western Scottish populations, which have deep historical links through time (Gilbert et al., 2017a).

1.7 Scope of this thesis

After a review of the current literature, several questions about the processes of population movements into Britain remain. Although population replacements during the Neolithic and Bronze Age have already been suggested (Brace et al., 2018; Olalde et al., 2018), it remains unknown what happened to the replaced indigenous populations. Possible introgression events during the Bronze Age to Iron Age transition are yet to be discovered. Similarly, ancient DNA studies have given glimpses of the genetic composition of the Roman period in Britain and their similarities and differences to Iron Age and Anglo-Saxon populations, but sample numbers are still very small and from few archaeological sites. Analyses of the genetic composition of individuals from the Viking period are also missing from the genetic history of the British Isles. The main objective of this thesis was to gain further insights into the genetic diversity and human migration events that can be learned from ancient British samples across these time periods, ranging from the Neolithic to the present, and from the south to the north of Britain, using whole genome sequencing techniques.

Chapter 2 describes the analysis of eight Neolithic individuals from Strathglebe on the Isle of Skye. One tooth sample turned out to be broken at the root and was thus excluded from sample preparation and analysis. Overall, genome coverage of the samples was very low, with only one sample producing over 10,000 SNPs and thus being suitable for genome-wide analysis. This individual showed most similar ancestry proportions to other Neolithic individuals from Europe. Uniparental markers for the seven Neolithic individuals were analysed and identified as belonging to ancient European mitochondrial lineages.

In Chapter 3, 25 individuals from the Bronze Age cemetery at the Links of Noltland, on Westray, Orkney, and three individuals from an Iron Age cemetery at Knowe of Skea, also on Westray, were analysed for both uniparental markers and autosomal data. Familial relationships among the individuals within the Bronze Age cemetery were investigated, and showed that most individuals were likely first-degree related, especially those buried within a large boat-shaped grave. No connection based on the female line of descent could be observed, suggesting patrilocality. Familial relationships were also identified among the three Iron Age individuals from the Knowe of Skea.

Genome-wide analysis of all samples with high enough coverage showed that both Bronze and Iron Age individuals cluster closest with other European Late Neolithic/Bronze Age individuals and show significantly similar admixture patterns, suggesting a continuous ancestry throughout the Bronze and Iron Ages on Westray.

Chapter 4 describes the analysis of a Bronze Age Bell Beaker individual from Low Hauxley, Northumberland, England. Interestingly, the individual showed a small proportion of ancestry most similar to ancient Levantine Bronze Age and modern North African populations, suggesting possible long-distance migrations during the Bell Beaker period.

Chapter 5 describes the analysis of maternal relationships between an adult female and a foetus and a perinate buried within the blockage of a stairwell to a cave entrance, at the Iron Age site of High Pasture Cave, Skye, Scotland. Due to the very low-coverage genomes retrieved from the bone fragments of the foetus and the perinate, only their mitochondrial genomes could be analysed for a possible maternal relationship between the individuals. The mitochondrial genome coverage was high enough to allow detailed comparisons of the mitochondrial haplotypes, and analysis suggested that the female was most likely to be the mother of the foetus, but not the perinate.

Chapter 6 describes the analysis of a rather unusual burial of an adult male in the Rosemarkie Cave, Black Isle, Scotland in the Pictish period. The murdered individual was buried with several big stones holding him down within the burial, as if to prevent him from returning from the dead. Genetic analysis showed that, despite this unusual treatment, he was likely a local, as he had typical northern European mitochondrial and Y-chromosome haplotypes. A comparison with the adult female from High Pasture Cave (discussed in Chapter 5), and published ancient and modern autosomal data, showed that both Scottish individuals displayed similar ancestry to Late Neolithic/Bronze Age European people. Although this only includes two adults, the results are suggestive of a possible continuous population from the Late Neolithic to the Pictish era in Scotland.

In Chapter 7, 16 individuals from a post-Roman cemetery at Worth Matravers were analysed for their genetic kinship, using both uniparental markers and

autosomal data. Several first- and second-degree kin relationships were identified across the cemetery. The majority clustered within modern-day European variation, whereas one individual also exhibited Near Eastern and/or North African ancestry. This was reflected in his Y-chromosome haplogroup - although he belonged to a typical European mitochondrial haplogroup, he had a Near Eastern/North African Y-chromosome. This individual highlights the diversity during the post-Roman period, and the possible long-distance migration of individuals.

Chapter 8 describes the analysis of an Early Anglo-Saxon cemetery at West Heslerton, North Yorkshire, England, which is located at a site that was already in use during the Bronze and Iron Age. Individuals from the Bronze Age (n = 3), Iron Age (n = 2) and the Anglo-Saxon cemetery (n = 9) were analysed in order to compare their uniparental markers and autosomal data. Although the Iron Age individuals were excluded from autosomal analysis due to low coverage, a population shift could be observed between the Bronze Age and the Anglo-Saxon period.

In Chapter 9, genetic analysis of a mutilated skull was used to accompany archaeological investigations on an Anglo-Saxon individual excavated at Oakridge, Basingstoke, England. As mutilation was typically a form of extreme punishment during the Late Anglo-Saxon era, it was surprising to find that the individual, whose nose had deliberately been cut off, was a young woman. From stable isotopic analysis, she was probably not local to the Hampshire area, but possibly from either northern England or southern Scandinavia. In the overall PCA she clustered closest with Bronze Age individuals from Links of Noltland in Orkney.

Two additional chapters with preliminary results can be found in the appendix (Appendix B and C), which focus on the modern phylogeography of the British Isles and on the dissemination of major European mitochondrial haplogroup H, respectively. Mitochondrial haplogroup frequencies were compared and founder analysis was run. The haplogroup composition among the countries within the British Isles varied, with Wales being rather different to other areas in the UK. Founder analysis of H3 showed that the oldest arrivals date to $\sim$8 and $\sim$7 kya in Britain, for central Europe and Iberia as source populations, respectively. Lineages with the biggest impact during

these migrations were very similar between the two source populations (Appendix B).
Phylogenetic trees of subhaplogroups of H were built and branches dated using ρ. The phylogenetic trees showed the likely origins of the haplogroups analysed and their distribution (Appendix C).

Chapter 2

Neolithic human remains from Strathglebe, Isle of Skye, Scotland

2.1 Introduction

The Neolithic first arrived in Britain *c.* 6,000 years ago, a thousand years after its arrival in adjacent areas of north-western Europe (Gkiasta et al., 2003). The migration patterns and cultural changes associated with the Neolithic transition in Britain have been discussed extensively (e.g. Thomas 1988; Sheridan 2010), but large scale genomic analyses of ancient British populations have added a new layer to the previous archaeological picture of the prehistory of the British Isles. The recent analysis of over 70 Neolithic individuals from across Britain found a significant population change from Mesolithic hunter-gatherers to Neolithic farmers (Brace et al., 2018). Of these samples, 37 were from Scotland and these showed the highest admixture proportions of western hunter-gatherers (WHG) compared to the other regions of the British Isles. Generally, little introgression from British hunter-gatherers could be inferred in the analysed British Neolithic samples, compared to inferred admixture with hunter-gatherer lineages brought in from the continent (Brace et al., 2018). However, this excludes the possibility of local adoption, especially, when comparing the different levels of introgression between Scotland, England and Wales. Large-scale studies, such as the above, add important information to the overall picture of the population structure of the British Isles, but they tend to ignore local, familial relationships and the stories behind the analysed individuals.

During a wider landscape survey, which was centred around the excavation of High Pasture Cave on the Isle of Skye (Scotland) (Figure 2.1), the remains of a degraded cairn were recorded. The assemblage of human remains found in the cairn were believed to be associated with the Neolithic as two leaf-shaped arrowheads were found amongst the remains. As the interred

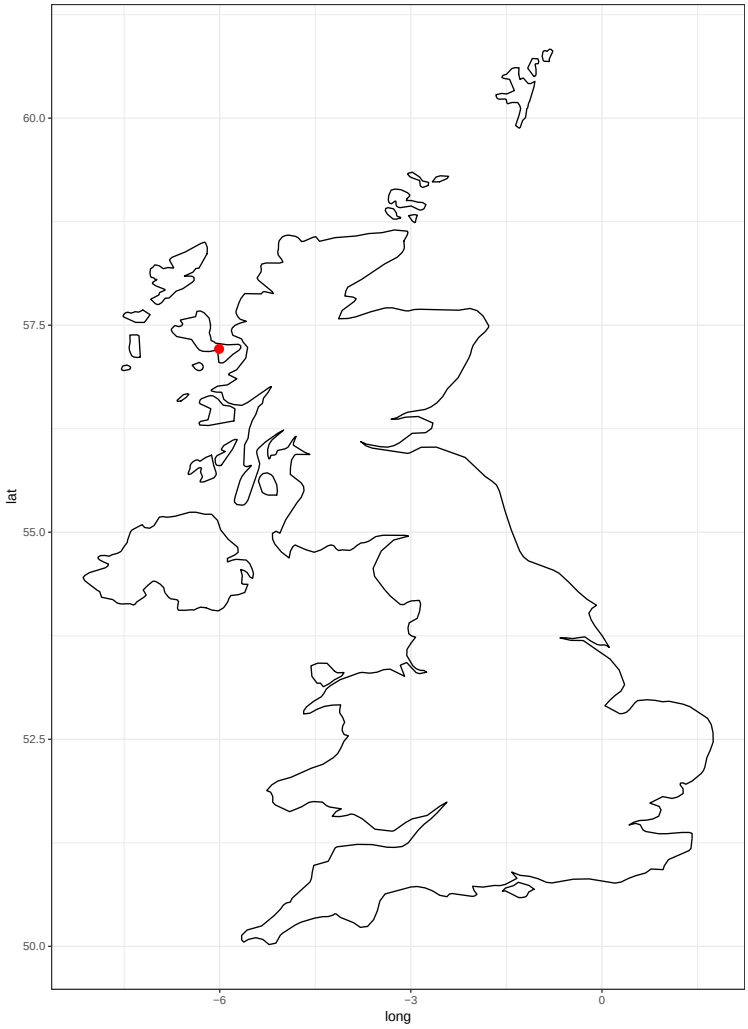

FIGURE 2.1: The location of Strathglebe within the British Isles.

remains were from disarticulated skeletons, it was difficult to determine the number of individuals buried within the cairn. However, based on the number of cranial elements, a minimum of six individuals was estimated. After further analysis of the remains, eight teeth were selected for ancient DNA (aDNA) analysis, stable isotope analysis and radiocarbon dating to confirm the age of the assemblage. The analysis of these individuals should allow for a more localised story of the Neolithic in the Isle of Skye, giving an insight into familial structures and maternal lineages present during this period in Scotland.

2.2 Materials and Methods

The human remains found in the degraded cairn were found in disarticulated bone and teeth mixtures, and a total of eight molars were selected to exclude the possibility of sampling the same individual twice (Table 2.1). The teeth were sampled for genetic and dietary stable isotopic analysis. One tooth (KD030) turned out to be broken at the root and was excluded from DNA analysis, as the amount of retrieved tooth powder was too low and, therefore, this sample was only used for dietary stable isotopic analysis. Tooth powder from KD027 was used for radiocarbon dating.

TABLE 2.1: Processed samples from Strathglebe. Analysis type: M – Macrogen; N/A – excluded genetic from analysis.

DNA code	DNA sample	Analysis type	Era	Sample code
KD023	LRM1	M	Neolithic	SG2 / N2 / Find 03 (sample 1)
KD024	LLM2	M	Neolithic	SG2 / S2 / Find 14 (sample 2)
KD025	LR?M1	M	Neolithic	SG2 / S1 / Find 06 / Context 1 (sample 3)
KD026	UL?M1?	M	Neolithic	SG2 / N3 / Find 50 / Context 3 (sample 4)
KD027	L?L?M1?	M	Neolithic	SG2 / N4 / Find 51 / Feature B (sample 5)
KD028	LR?M1	M	Neolithic	SG2 / S03 / Find 49 (sample 6)
KD029	LLM1	M	Neolithic	SG2 / E02 / Find 43 (sample 7)
KD030	URM3	N/A	Neolithic	SG2 / S2 / Find 48 (sample 8)

2.2.1 Sampling and DNA extraction

The sampling took place at the Ancient DNA Facility at the University of Huddersfield under dedicated clean-room conditions. Full body suits, hairnets, gloves and face masks were worn throughout the drilling, extraction and library preparation processes. All tools and surfaces were constantly cleaned with LookOut® DNA Erase (SIGMA Life Sciences), as well as with bleach, ethanol and long exposures to UV light. The tooth surfaces were decontaminated by UV radiation for 10 minutes on each side, followed by cleaning with 5µm aluminium oxide powder using a compressed air abrasive system. Each root was removed using a cutting saw attached to a hobby drill, and this was then shaken with a steel ball inside a metal shaker in a Mixer Mill (Retsch MM400) for 30 seconds at 30 Hz/second. DNA was extracted from approximately 150mg of the root powder produced, following the protocol by Yang et al. (1998) with modifications by MacHugh et al. (2000). Blank controls were included throughout the sampling procedure and extraction to allow quantification of possible contamination.

2.2.2 Library preparation and sequencing

Next-generation sequencing libraries were constructed from DNA extracts using the method by Meyer et al. (2010) with modifications outlined in Gamba et al. (2014) and Martiniano et al. (2014). The DNA extracts were treated with the USER enzyme (NEBNext) prior to library preparation, by adding 5 µl of USER enzyme (1U/µl), mixing and incubating for 3 hours at 37 °C. All DNA purification steps were performed using the QIAQuick MinElute purification kit (Qiagen) following the manufacturers protocol, with the modification of adding 0.05% Tween 20 (Fisher BioReagents) to the Elution Buffer. Libraries were single-indexed, and blanks were included.
In brief the method was as follows, T4 DNA polymerase buffer (Thermo Scientific) was used instead of Tango buffer in the Blunt-end repair step. Bst polymerase activity was heat inactivated by incubating the libraries for 20 minutes at 80°C. Indexing amplifications were set up using Accuprime *Pfx* Supermix (Life Technology), primer IS4 (0.2µM), a specific indexing primer (0.2µM) and 3 µl of sample library, with a total reaction volume of 25 µl. Amplification was run under the following thermal cycling conditions: 5 minutes at 95 °C; 14 cycles of 15 seconds at 95 °C, 30 seconds at 60 °C and 30 seconds at 68 °C; and a final extension step of 5 minutes at 68 °C. The resulting amplification product was purified using the QIAQuick MinElute purification kit (Qiagen) described above.
For the second amplification round Accuprime *Pfx* Supermix (Life Technology) was used, together with primers IS5 (10µM), IS6 (10µM) and 2.5 µl of sample library. Amplification took place under the following thermal cycling conditions: 30 seconds at 98 °C; 10 cycles of 20 seconds at 98 °C, 30 seconds at 60 °C, 40 seconds at 72 °C, and a final extension of 5 minutes at 72 °C. The PCR product was purified as described above. Amplifications were quantified using a Qubit 3.0 Fluorometer, and then analysed using an Agilent 2100 Bioanalyzer High Sensitivity DNA kit. Libraries were pooled equimolarly, as twelve libraries were sequenced per lane. NGS libraries were sequenced on an Illumina HiSeq4000 (100 base pair, paired-end sequencing; Macrogen, South Korea).

2.2.3 Radiocarbon dating

Radiocarbon dating of sample KD027 was carried out by Dr. Peter Ditchfield at the Oxford Radiocarbon Accelerator Unit. This was processed using the standard Oxford Laboratory protocol (Ramsey et al., 2002; Ramsey

et al., 2004a; Ramsey et al., 2004b). The resultant data was calibrated using OxCal v.4.3.2 (Ramsey et al., 2010), using the IntCal13 calibration curve. IntCal13 represents the mid-latitude northern hemisphere atmospheric reservoir, which consists of compiled measurements of tree rings, plant macrofossils, speleothems, corals, and foraminifera from independent dating (Reimer et al., 2013).

2.2.4 Dietary stable isotope analysis

Stable isotope analysis was undertaken by Dr. Peter Ditchfield at the University of Oxford, according to the following protocol.
Collagen for carbon and nitrogen stable isotopic analysis was prepared from the dentine of the tooth crown. The sample was demineralised using 10ml aliquots of 0.5M HCl solution at 4°C. The acid was changed at 48 hour intervals until no further reaction was seen. The sample was then rinsed three times with milli-µ ultra-pure water and placed in 10ml of pH3 water at 75°C for 48 hours. The sample was filtered using an Eezee™ filter, and the supernatant liquid decanted into a Nalgene™ tube with a temporary Parafilm™ cover. The sample was pre-frozen at -40°C prior to freeze drying in a Zirbus VaCo5 freeze drier fitted with an oil free vacuum system for 72 hours.
The resulting purified collagen was weighed out for analysis using *c*. 1mg aliquots weighed into pre-cleaned tin capsules. Samples were combusted on a Sercon GSL elemental analyser system using a helium carrier gas with a flow of approximately 80ml per minute. A 2% split of the gases evolved was analysed for nitrogen and carbon stable isotopic composition using a Sercon $-20/22$ gas source mass spectrometer. Isotopic values as well as elemental abundances and carbon-to-nitrogen ratios were calibrated against an in-house alanine standard, which itself is routinely measured against international standards (USGS 40 and USGS 41 glutamic acid, whose values are traceable back to the V-PDB and AIR international standards for carbon and nitrogen, respectively). Further aliquots of the alanine standard were used to monitor and correct for instrumental drift. The sample was run in triplicate. Stable isotopic results are reported in delta notation relative to V-PDB for carbon and AIR for nitrogen. Replicate analysis of the alanine in-house standard gave the following results (n= 10 measurements): $\delta^{13}C = -27.15 \pm 0.13‰$, expected value $-27.11‰$; $\delta^{15}N = -1.55 \pm 0.15‰$, expected value $-1.56‰$. This suggests that the individual values obtained during the analyses reported here are typically accurate to be better than $\pm 0.1‰$ for both $\delta^{13}C$ and $\delta^{15}N$.

2.2.5 Data processing and read mapping

The resulting NGS reads were trimmed using AdapterRemoval version 2.1.7 (Schubert et al., 2016), to remove the adapters from the read pairs, trim Ns, remove low quality bases and merge the reads (`-trimns -trimqualities -collapse -adapter1 AGATCGGAAGAGCACACGTCTGAACTCCAGTCAC -adapter2 AGATCGGAAGAGCGTCGTGTAGGGAAAGAGTGT`). BWA aln, version (0.7.12-r1039) (Li et al., 2009a), was used to map reads to the human mitochondrial genome (rCRS, NC_012920.1; Andrews et al. 1999) and the human reference genome (UCSC hg19), filtering by base quality 15 and disabling seed length as recommended for aDNA data (Schubert et al., 2012). Samtools version 1.3 was used to sort, and filter reads, and to remove PCR duplicates. DNA damage patterns were assessed using mapDamage 2.0 (Jónsson et al., 2013) and bamdamage (Malaspinas et al., 2014). Picard tools version 2.18 (`http://broadinstitute.github.io/picard`) was used to add read groups to the sequencing reads aligned to hg19. Variants were called using samtools mpileup with -B -q20 and -Q20 and pileupCaller with the published Lazaridis et al. (2016) and Olalde et al. (2018) datasets as reference panel. The sequencing quality was assessed using FastQC v0.11.5 (Andrews, 2016) and qualimap version 2.2.1 (Okonechnikov et al., 2016). Samtools mpileup and bcftools v.1.3 were used to create a consensus fastq file of the alignment to the rCRS. SEQTK (v.1.2-r102-dirty) was used to convert the fastq file into fasta format. The mitochondrial contamination was estimated using schmutzi (Renaud et al., 2015).

2.2.6 Bioinformatic analysis

The genetic sex was determined using a script published by Skoglund et al. (2013), and in cases where the sex could not be assigned using this method karyotype plots and the Skoglund score (Skoglund et al., 2015) were used. For the mitochondrial haplotype assignment, variant lists of each sample were extracted from the consensus sequences and uploaded to HaploGrep 2 (Weissensteiner et al., 2016). For the paternal lineage prediction Yleaf was used (Ralf et al., 2018).

In order to compare the newly generated ancient data to published modern and ancient human populations, known informative SNP positions of the publicly available Lazaridis et al. (2016) and Olalde et al. (2018) datasets were used and SNPs were filtered as described previously (Lazaridis et al.,

2016; Mathieson et al., 2018; Olalde et al., 2018). Variants in linkage disequilibrium were filtered using the -indep-pairwise option in PLINK v0.67 with the parameters 200, 25 and 0.4. Principal component analysis was run using smartpca of the EIGENSOFT package (Patterson et al., 2006; Price et al., 2006) and plotted with R version 3.4.4 (R Core Team, 2018). A combined dataset of the Neolithic genotypes, together with the reference panel, was run using ADMIXTURE (Alexander et al., 2009) for ancestral population numbers from K=2 to K=14, with cross-validation enabled (-cv flag).

2.3 Results

2.3.1 Sequencing results

All seven libraries of the sampled individuals produced genetic data. The endogenous content of the samples ranged from 5.83 to 26.73%. The duplication rate was generally very low, with <0.1%. The overall genome coverage was very low, as all libraries produced less than 0.1x genome coverage. All results are given in Table 2.2. Contamination estimates of the negative controls, as well as the overall contamination fraction of the sequencing lane were very low (for details see Appendix D).

TABLE 2.2: Sequencing results of the Neolithic individuals from Strathglebe. 'SNPs' denotes the number of SNPs called with the published datasets as reference panel.

Sample ID	Read count	Endogenous content in %	Duplication rate in %	Genome coverage	SNPs
KD023	58,063,490	5.83	0.0733	0.0113	3,598
KD024	79,832,908	6.95	0.0848	0.0157	5,802
KD025	43,700,926	8.15	0.0754	0.0087	1,568
KD026	90,603,286	26.73	0.0910	0.0978	41,748
KD027	80,631,004	7.21	0.0846	0.0193	5,978
KD028	55,547,446	7.65	0.0691	0.0100	2,680
KD029	62,971,140	11.76	0.0728	0.0111	4,515

2.3.2 Radiocarbon dating

The uncalibrated radiocarbon date was 4569 ± 35 bp (OxA-37513), which corresponds to 3495-3104 calibrated BC (95.4%) shown in Figure 2.2.

2.3.3 Dietary stable isotope analysis

In order to identify the type of diet the Strathglebe individuals were eating, dietary stable isotopes were analysed and compared to four other Neolithic sites from western Scotland: Carding Mill Bay, Oban (n = 11); Clachaig A,

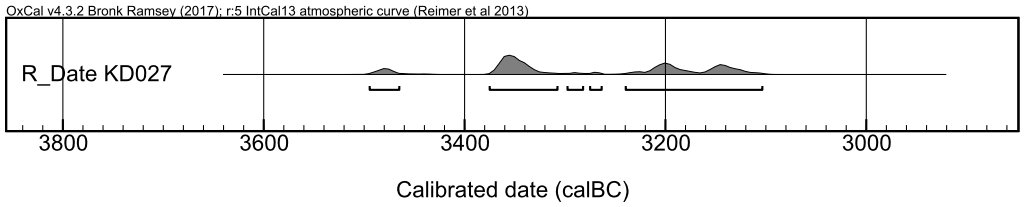

FIGURE 2.2: Calibrated radiocarbon date of KD027.

West coast of Scotland (n = 6); Crarae, Inveraray (n = 3); and Raschoille Cave, Oban (n = 9) (Schulting et al., 2002b; Bownes, 2018). The resulting plot is shown in Figure 2.3.

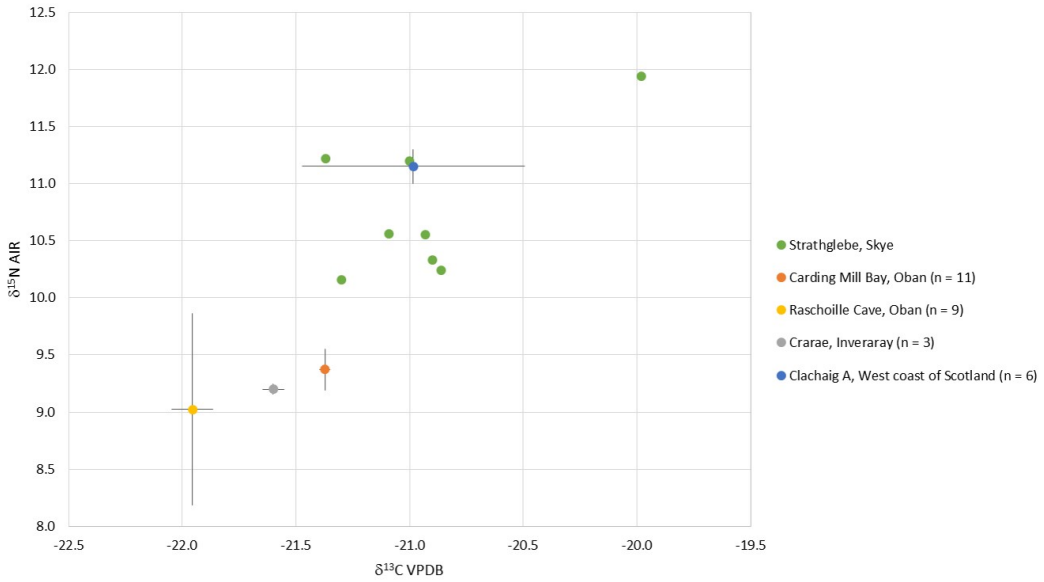

FIGURE 2.3: Dietary stable isotope data of the Neolithic Strathglebe individuals, compared to four other Neolithic human assemblages from western Scotland (Schulting et al., 2002b; Bownes, 2018).

2.3.4 Genetic sex determination

Using the Skoglund script (Skoglund et al., 2013), the genetic sex could only be determined for one individual (KD026), which was a male. For individual KD029, the sex determination was consistent with XX, but not XY. No sex could be assigned to any other individual using this method. For the undetermined individuals, karyotype plotting was used and the percentage of chromosome X reads was calculated following Skoglund et al. (2015) (for details see Appendix E). Following this approach, the genetic sex of all previously undetermined individuals could be estimated (Table 2.3).

TABLE 2.3: Karyotype-based genetic sex determination using the Skoglund score (Skoglund et al., 2015).

Sample ID	X-chromosome in %	Sex determination
KD023	78.6	XX
KD024	82.5	XX
KD025	60.0	XY
KD027	53.2	XY
KD028	73.3	XX
KD029	87.3	XX

2.3.5 Mitochondrial genome analysis

The mitochondrial haplotype analysis revealed that two haplogroups are shared among four individuals, T2b and U5b2c. Haplogroups represented by only one individual within this assemblage are J1c1, H1c and H5b (Table 2.4). Individual haplotypes for all samples analysed can be found in Appendix F.

TABLE 2.4: Mitochondrial genome analysis of the Strathglebe individuals.

Sample ID	Mitogenome coverage	Std deviation	mtDNA Haplogroup	Overall rank
KD023	13.0923	3.6492	J1c1	0.9975
KD024	23.0202	4.7622	T2b	0.9902
KD025	0.8991	1.0684	H1c	0.6067
KD026	22.1220	4.5654	U5b2c	0.9222
KD027	11.9543	3.6918	U5b2c	0.9277
KD028	15.4872	3.8070	T2b	0.9902
KD029	16.6424	4.1540	H5b	1.0000

2.3.6 Y-chromosome analysis

Only one sample (KD026) had enough coverage to be securely identified as male. This sample had four 'most downstream' predictive markers for Y-chromosome haplogroup I, namely M258, CTS4088, CTS4982 and L751, with a total of 1,672 detected SNPs (for details see Appendix G Table G.1). The number of retrieved predictive markers for chromosome Y were too low in the other two putative male samples (KD025 and KD027).

2.3.7 Principal component analysis

Principal component analysis (PCA) was run for KD026 only, due to the number SNPs overlapping with the Lazaridis et al. (2016) dataset. A PCA

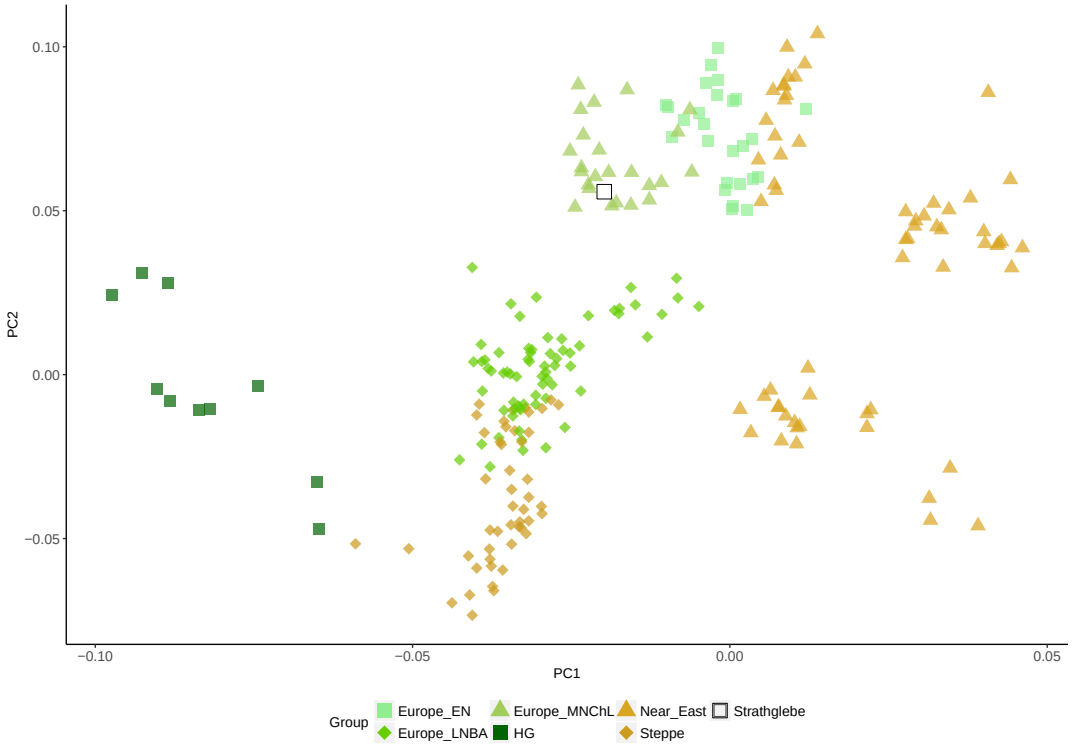

FIGURE 2.4: Principal component analysis of the Strathglebe individual, with previously published ancient samples of Lazaridis et al. (2016) projected onto the first two principal components.

was run on the sample merged with the Lazaridis dataset. The sample is projected on the first and second principal components of the published dataset (Figure 2.4).

2.3.8 ADMIXTURE analysis

ADMIXTURE was run for KD026 merged with the complete Lazaridis et al. (2016) and Olalde et al. (2018) datasets, with cross-validation between *K* values 2 to 14, with *K*=12 giving the lowest standard error (Appendix H) and therefore being the sensible modelling choice (Figure 2.5).

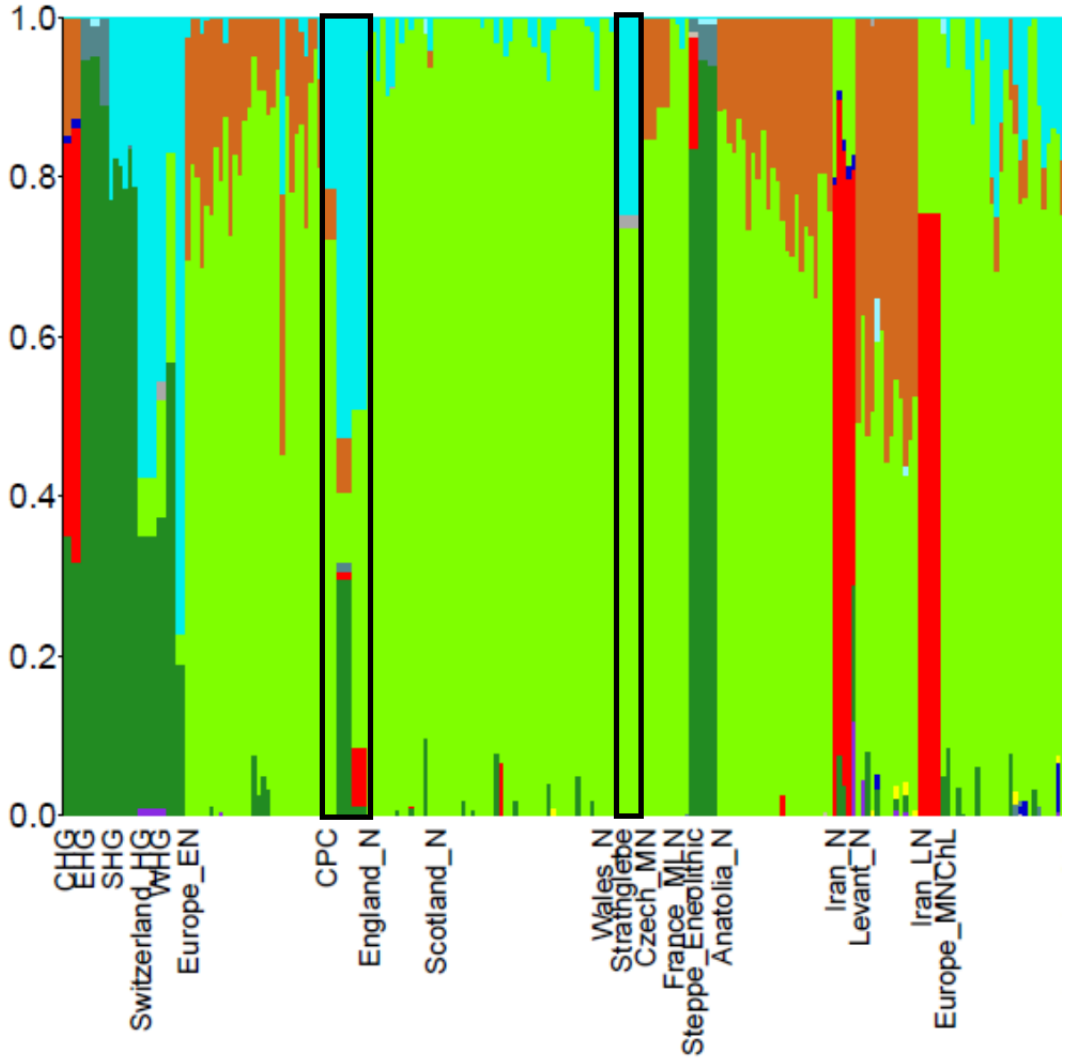

FIGURE 2.5: ADMIXTURE analysis of the Strathglebe individual (KD026), with previously published ancient samples of Lazaridis et al. (2016) and Olalde et al. (2018) for K=12. Figure displays relevant subsection of Figure 10.2. Abbreviations used: E: Early, M: Middle, L: Late, HG: Hunter-Gatherer (C - Caucasus, E - Eastern, S - Scandinavian, W - Western), N: Neolithic, ChL: Chalcolithic, CPC: Carsington Pasture Cave.

2.4 Discussion

2.4.1 Distinguishing between individuals

Since the samples originated from loose teeth, and because it was not possible to sample the same tooth type from each (potential) individual, the genetic data was compared in order to possibly distinguish between individuals. Furthermore, one sample (KD027) was dated in order to verify the archaeological determination of the assemblage belonging to the Neolithic. The radiocarbon date of KD027 of 4569 $\pm$ 35 bp (OxA-37513) confirmed the Neolithic origin of these samples.
The two samples belonging to mtDNA haplogroup U5b2c were both determined as male, and unfortunately, the Y-chromosome coverage of KD026 and KD027 was too low to compare the Y-chromosome haplogroup and check for differences to exclude the possibility of them having originated from the same individual. However, KD027 was from Feature B in a group with several other teeth, whereas KD026 was from a different context. Therefore, they are most likely different individuals. Similarly, KD024 and KD028 were both determined as female and both belonged to mtDNA haplogroup T2b. As they were sampled from a lower left second molar and a lower right(?) first molar, respectively, it could not be excluded in this case that these two samples originated from the same individual.

2.4.2 Neolithic diet in Strathglebe

The dietary stable isotope data showed that the people at Strathglebe were eating a high protein diet, as shown by their high nitrogen values. They are eating a similar diet to the people from Clachaig A on the west coast of Scotland, but both sites are different to Carding Mill Bay and Raschoille Cave in Oban, and Crarae in Inveraray. These latter people have little to no marine component in their diet (Schulting et al., 2002b), whereas Strathglebe and Clachiag A show more evidence of a fish-rich diet. KD025 has the highest nitrogen value, which, along with the increased carbon result, suggests that this individual was eating a marine diet.

2.4.3 Maternal lineages

The genome coverage was too low to run any admixture analysis, so it was not possible to compare the genomes of the studied individuals with previously reported Neolithic individuals from Britain. Nevertheless, the low coverage data did allow for analysis of maternal familial relationships amongst the assemblage. The seven individuals analysed in this study were identified as belonging to five different mtDNA haplogroups; i.e. H1c, H5b, J1c1, T2b and U5b2c, with both T2b and U5b2c seen in two samples each.

2.4.3.1 Haplogroup H

Two individuals belong to H1c and H5b, sublineages of the major European mtDNA haplogroup H (more details on this haplogroup can be found in Appendix C). The sample (KD025) that was determined to belong to mitochondrial haplogroup H1c only had a rank of 0.60, which indicated inaccuracy. After manual checking of the sequence only the defining mutation for H1c could be found. The sample did not show the defining mutation for H1 G3010A, although the postion was covered. Instead, the positions for both defining mutations of H were not covered, therefore, any assumptions made on the presence of H1c in the Neolithic on the Isle of Skye need to be made with caution. H1 is the most frequent subhaplogroup of H and has a similar star-like structure to H. Its frequency peaks are in Iberia and it is argued that H1 spread with the Neolithic migrations from the ice age refuge in Iberia into Europe. In modern-day Britain haplogroup H1 has a frequency of $\sim$30%.
Haplogroup H5, on the other hand, is less frequent than H1, although it is still one of the more frequent subclades of haplogroup H, accounting for $\sim$8% in modern-day Britain (see Appendix B). Its highest frequencies are in south-eastern Europe (mainly Italy), Latvia and Wales. Haplogroup H1c has previously been reported in Mesolithic/Neolithic remains from Sweden (Skoglund et al., 2014), from the Neolithic in England (Cheddar, Somerset) and Scotland (Oban, Argyll and Bute) (Olalde et al., 2018) and in the Bronze Age from England (Stockton-On-Tees, North Yorkshire) (Olalde et al., 2018), Germany (Knipper et al., 2017) and Latvia (Mittnik et al., 2018).
While H1c has previously been found in the British Isles dating as far back as the Neolithic, H5b has, to date, not been reported from ancient human remains from the British Isles. Neolithic remains belonging to H5b were found in Bulgaria (Mathieson et al., 2018) and Germany (Brotherton et al.,

2013). Human remains from the Bronze Age were found in the Czech Republic (Olalde et al., 2018) and Russia (Mathieson et al., 2015), whereas two Iron Age individuals belonging to H5b were found in Moldova (Juras et al., 2017). The newly reported H5b mitochondrial genome from the Isle of Skye is important for the analysis of H5 and its arrival in the British Isles, as its current distribution in the Neolithic suggests a contribution of mitochondrial lineages from central Europe into the British Isles.

2.4.3.2 Haplogroups J and T

Mitochondrial haplogroups J and T both originated in the Near East and spread into Europe after the peak of the LGM (Pala et al., 2012), however, multiple dispersals during the Late LGM and the Neolithic have been suggested as well (Pereira et al., 2017). The main subclades of both haplogroups that are seen as signals for the major expansions in the Late Glacial period are J1c, J1b1a, J2a1, T1a1, T2a1b and T2f1, as well as T2b and T2e, which signal the expansions in the immediate postglacial period (Pala et al., 2012). Haplogroup J1 is in general mainly Near Eastern, whereas its subclade J1c is primarily European. Haplogroup J1c1, which has been identified in an individual from Strathglebe, has an age estimate of $\sim$12 kya (Pala et al., 2012). T2b is the major European clade of haplogroup T and comprises of about half of all T2 seen within Europe. T2b likely dispersed in Europe during the Early Neolithic and has an age estimate of $\sim$10 kya. Similar to the major European haplogroup H (see Appendix C), T2b is quite star-like and very widespread within Europe (Pala et al., 2012). Both J1c and T2b have been reported from Neolithic and Bronze Age remains throughout Europe.
J1c has been identified in Neolithic remains from England (Brace et al., 2018), Hungary (Gamba et al., 2014), Germany, (Haak et al., 2015; Lipson et al., 2017) and Bulgaria (Mathieson et al., 2018). Other remains from Germany (Knipper et al., 2017; Olalde et al., 2018), Hungary (Lipson et al., 2017), Romania and Ukraine (Mathieson et al., 2018), and the British Isles (Olalde et al., 2018) date to the Bronze Age. The subclade J1c1 has been mainly reported in Neolithic and Bronze Age remains from the British Isles and Spain, but was also found in Neolithic remains from Hungary, Greece and Macedonia (Gamba et al., 2014; Mathieson et al., 2015; Hofmanová et al., 2016; Lipson et al., 2017; Brace et al., 2018; Mathieson et al., 2018; Olalde et al., 2018). Haplogroup T2b has, to date, been reported in 41 ancient samples from the Neolithic, Chalcolithic, Bronze Age and Iron Age in Europe. The remains dating

to the Neolithic are from Austria (Mathieson et al., 2018), Bulgaria (Mathieson et al., 2018), England (Winterbourne Monkton, Wiltshire) (Olalde et al., 2018), Germany (Haak et al., 2015; Lipson et al., 2017), Hungary (Lipson et al., 2017), Turkey (Mathieson et al., 2015), and Ukraine (Nikitin et al., 2017; Mathieson et al., 2018). Bronze Age remains were found in Denmark (Allentoft et al., 2015), Hungary (Allentoft et al., 2015; Lipson et al., 2017; Olalde et al., 2018), Czech Republic (Allentoft et al., 2015; Olalde et al., 2018), Turkey (Lazaridis et al., 2017), Ukraine (Mathieson et al., 2018), Lithuania and Sweden (Mittnik et al., 2018), the British Isles (Biddenham Loop, Bedfordshire; Mortlake, London; Trumpington Meadows, Cambridge; Stockton-On-Tees, North Yorkshire), Germany and Spain (Olalde et al., 2018). Furthermore, one Iron Age individual from Moldova (Juras et al., 2017) was found belonging to T2b.

2.4.3.3 Haplogroup U5

The mtDNA haplogroup U5 is the most ancient European maternal haplogroup and is argued to have arisen in Europe (Malyarchuk et al., 2010b). Its most ancient identified subhaplogroup is U5b2, which dates to $\sim$24 kya, suggesting a pre-LGM divergence within Europe (Malyarchuk et al., 2010b). Haplogroup U5 has been found in ancient individuals from the Czech Republic and Belgium (Fu et al., 2016; Posth et al., 2016), all dating to the Upper Palaeolithic. U5b* is mainly reported from the Late Mesolithic and Early Neolithic of the British Isles (Brace et al., 2018; Olalde et al., 2018), but also from the Late Chalcolithic in Hungary (Lipson et al., 2017). To date four ancient individuals belonging to haplogroup U5b2* have been reported. One individual from the Early Neolithic in Hampnett, Cheltenham, England, (Brace et al., 2018) and three individuals from the Ukraine dating to the Mesolithic (Jones et al., 2017; Mathieson et al., 2018). Within the subclade of U5b2c*, nine ancient individuals have been reported to date. These samples were found in the Mesolithic in Serbia, the Late and Middle Neolithic in Hungary, the Chalcolithic/Early Bronze Age in the Czech Republic, the Bell Beaker period in Germany and the Corded Ware in Estonia (Gamba et al., 2014; Allentoft et al., 2015; Lipson et al., 2017; Saag et al., 2017; Mathieson et al., 2018; Olalde et al., 2018).

2.4.4 Paternal lineages

One of the individuals from the Late Neolithic in Hungary that belongs to haplogroup U5b2c has the Y-chromosome haplogroup I2a1, and appears to share a similar ancestry as the male from this study (KD026). Although the coverage of the Y-chromosome was too low to further specify the predicted Y-chromosome haplogroup, the reported individual likely belongs to Y haplogroup I. Virtually absent anywhere else, Y-chromosome haplogroup I is the only major clade that is widespread in Europe (Rootsi et al., 2004). The phylogeography of haplogroup I suggests a European origin, most likely before the Last Glacial Maximum (LGM) (Semino et al., 2000), and thus a pivotal role of this lineage during the recolonisation of Europe after the LGM (Rootsi et al., 2004). The haplogroup is most common among modern day Scandinavian populations and those in the north-western Balkans (Rootsi et al., 2004).

2.4.5 Conclusions

Unfortunately, the coverage of the sequenced genomes was too low to securely determine the genetic sex of the studied individuals. A full Y-chromosome analysis of the single possible male individual was not possible, as a minimum coverage of the Y-chromosome is needed to predict the haplogroup. Thus, only one male individual could be analysed for both its maternal and paternal lineages. A comparative analysis of the presented Neolithic genomes with published genomes from the Neolithic in Britain and the European continent was only possible for one sample (KD026), due to the very low coverage of the genomes. In the PCA KD026 clustered closest with European Neolithic individuals, which was supported by the admixture analysis, that showed similar patterns of ancestry for the Neolithic individual from Strathglebe and European Middle Neolithic individuals from the Lazaridis et al. (2016) dataset, as well as to the Neolithic individual from the Carsington Pasture Cave (supplementary information in Appendix I).

Chapter 3

A Bell Beaker individual from Low Hauxley, Northumberland

3.1 Introduction

Over the past centuries, archaeological and palaeoenvironmental deposits have been lost to the sea due to the impact of coastal erosion (Waddington et al., 2016). The cliff face to the south of Low Hauxley, on the Northumberland coast (Figure 3.1), has been eroding for the past 30 years (Waddington et al., 2016). The main archaeological site occupies a slight natural hillock and is flanked to the north and south by separate organic sediment units, described as "peats", that would have originated as wetlands during the Neolithic period, around the 4th millennium cal. BC (Waddington et al., 2016). A team, led by Clive Bonsall, conducted a long-term investigation of the site between 1982 and 1988, which involved systematic excavation and extensive palaeoenvironmental work (Bonsall, 1984). Evidence for human activity dating from the Mesolithic through to the medieval period was found, including the remains of a Neolithic stone-built burial mound, or cairn, from which pottery sherds and cist burials with cremated human remains were eroding (Waddington et al., 2016). In addition, Mesolithic flint artefacts were found in a buried soil horizon underneath the cairn, and pottery was recovered from a later soil layer within the sand dune above the cairn.

Human remains, including a complete skeleton and a Beaker, were recovered from within the cairn, all from cist burials, made by digging pits through the ground surface and constructing well-made stone cist boxes with capstones that would have stood proud of the ground surface (Waddington et al., 2016). The inhumation (Burial 1) was removed from its cist through a small "side" slab on its north side (Waddington et al., 2016). The individual was a young, possibly male, young adult, aged between 12 and 16, crouched and facing towards the north. He was radiocarbon dated to the early part of

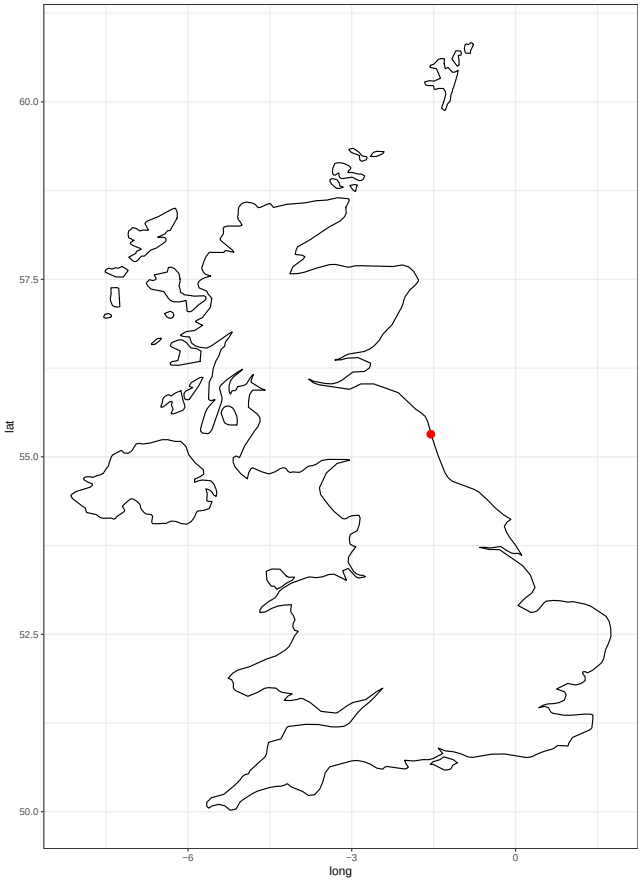

FIGURE 3.1: The location of Low Hauxley within the British Isles.

the Beaker period (3874 ± 32 bp; SUERC-49872; approximately 2466-2279 cal. BC) (Waddington et al., 2016), and appeared to have been accorded particular significance as a primary or founding burial. Two other cists contained cremated remains from two other people (Burials 2 and 3), who were not accompanied by a Beaker vessel. To date, there are no other instances where both cremation and inhumation remains accompanied by a Beaker have been reported at the same site (Waddington et al., 2016). The tops of the three cists would have remained visible after burial and they formed the first phase of the Low Hauxley cemetery, which can be directly associated with the Beaker people (Waddington et al., 2016). The genetic analysis of the Beaker inhumation can contribute to the understanding of the arrival of the Bell Beakers into Britain and their genetic heritage.

3.2 Materials and Methods

The left petrous portion of Burial 1 was sampled for DNA analysis at the Ancient DNA Facility of the University of Huddersfield, under dedicated

clean-room conditions. Two single-indexed libraries were prepared, and sequenced on an Illumina HiSeq 4000 (100 base-pair, paired-end sequencing; Macrogen, South Korea). The analytic steps, sample preparation and bioinformatic analyses followed as outlined in Chapter 2.

3.3 Results

3.3.1 Sequencing results

Sequencing results are displayed in Table 3.1.

TABLE 3.1: Sequencing results of the Low Hauxley sample. 'SNPs' denotes the number of SNPs called with the published datasets as reference panel.

Sample ID	Read count	Endogenous content in %	Duplication rate in %	Genome coverage	SNPs
Low Hauxley	69,129,236 & 53,129,192	16.00 & 19.05	1.39	0.0553x	21,101

3.3.2 Genetic sex determination

The genetic sex was determined as male. The score by Skoglund et al. (2015) gave a result of 'only consistent with XY but not XX' (Skoglund et al., 2013), and, therefore, karyotype-plotting (Figure 3.2), was undertaken, together with the calculation of the Skoglund score (Skoglund et al., 2015), which was 57.4% and, therefore, indicates a male.

3.3.3 Mitochondrial genome analysis

The haplotype of the presented ancient sample was determined as described in Chapter 2, using the rCRS as reference genome. The individual was found to have all the defining mutations of haplogroup T2e1a (Table 3.2). The full mutation list can be found in Appendix F.

3.3.4 Y-chromosome analysis

The Y-chromosome analysis gave R1b1a1a2 as the predicted haplogroup, with CTS7880, CTS5676, L820, L389, and CTS12972, as most downstream predictive markers (see Appendix G for more details).

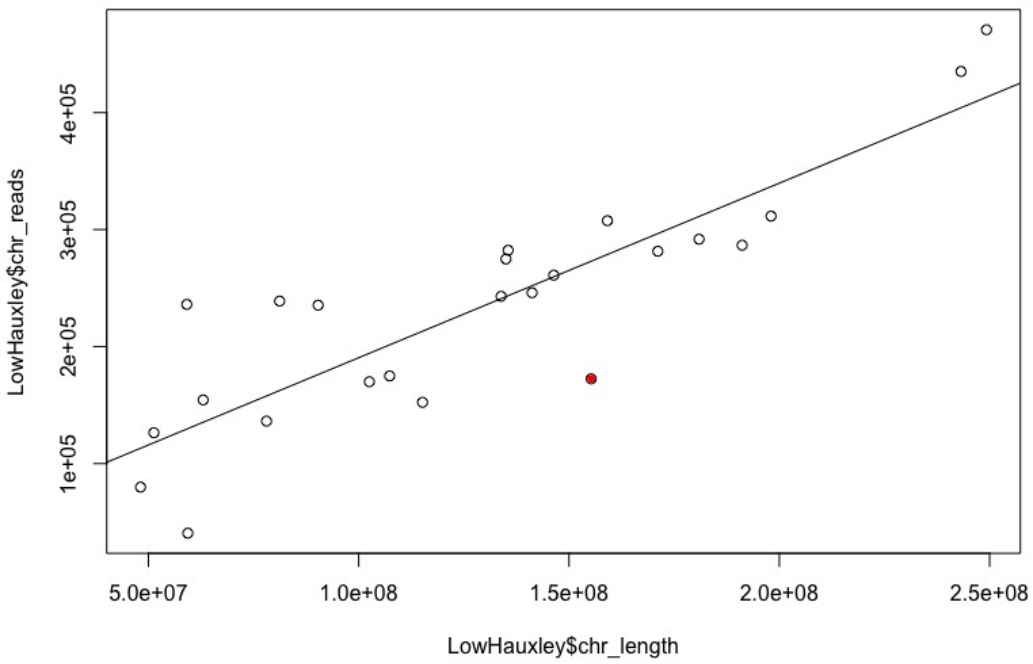

FIGURE 3.2: Karyotype plot of the Low Hauxley individual.

3.3.5 Principal component analysis

In the PCA, the individual of Burial 1 plots alongside published European Late Neolithic/Bronze Age samples used in Lazaridis et al. (2016) (Figure 3.3).

3.3.6 ADMIXTURE analysis

The ADMIXTURE cross-validation error for K=12 was the lowest (see Appendix H). The admixture plot is shown in Figure 3.4.

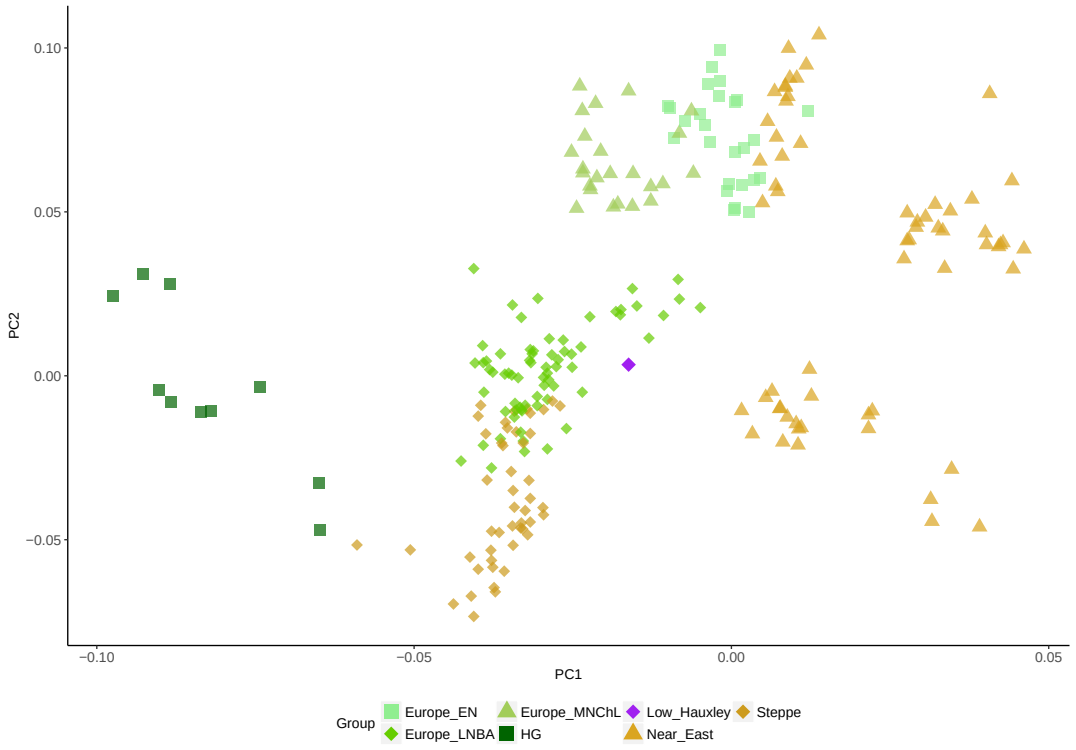

FIGURE 3.3: Principal component analysis of the Low Hauxley individual, with previously published ancient samples of Lazaridis et al. (2016) projected onto the first two principal components.

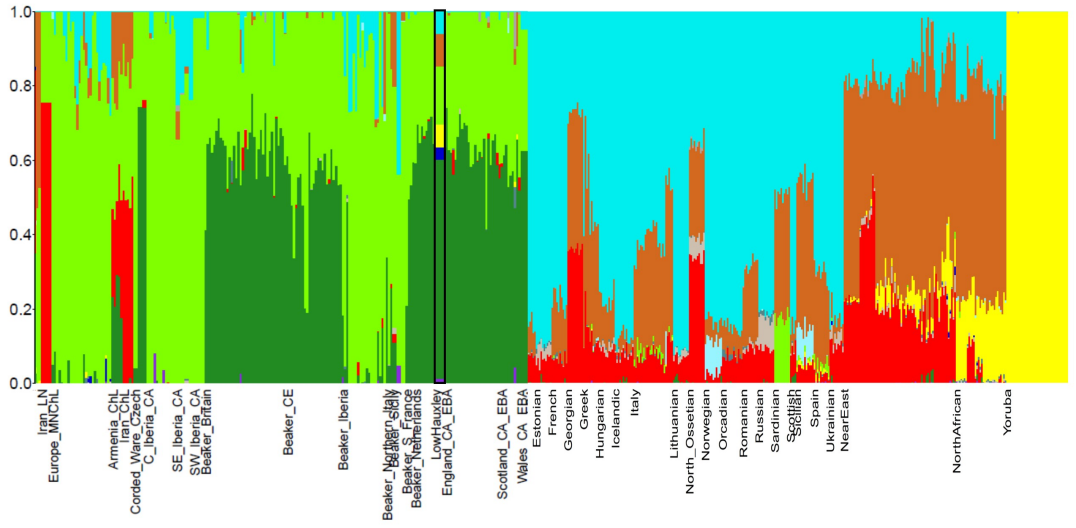

FIGURE 3.4: ADMIXTURE analysis of the Beaker individual from Low Hauxley, with previously published ancient Beaker and Copper Age samples of Lazaridis et al. (2016) and Olalde et al. (2018) for K=12. Abbreviations used: E: Early, M: Middle, L: Late, N: Neolithic, ChL: Chalcolithic, CA: Copper Age, BA: Bronze Age, CE: Central Europe, LON: Links of Noltland.

TABLE 3.2: Mitochondrial DNA haplogroup and mutations identified in the Low Hauxley individual.

Sample	Haplogroup	Average coverage	Polymorphisms
Low Hauxley	T2e1a	8.8633x	41T 73G 150T 263G 750G 1438G 1888A 2706G 4216C 4769G 4917G 7028T 8697A 8860G 10463C 11251G 11719A 11812G 13368A 14233G 14766T 14905A 15326G 15452A 15607G 15928A 16126C 16294T

3.4 Discussion

3.4.1 Genome coverage

The genome coverage of the Beaker individual from Low Hauxley was 0.0553x and allowed genome-wide analysis with published modern and ancient genomes, as well as detailed analysis of the uniparental markers. Although it is difficult to sex sub-adult remains using osteological methods, the individual was classified as male (Waddington et al., 2016). The genetic sex confirmed this identification.

3.4.2 Maternal and paternal lineage

The mitochondrial coverage was close to 10x and the complete genome was recovered. The individual was securely determined as belonging to haplogroup T2e1a. The subclade of T2, T2e, is a predominantly southern European and Mediterranean haplogroup (Pala et al., 2012), which has been found in Bell Beakers in central Europe and Bronze Age England (Olalde et al., 2018). Subhaplogroup T2e1a has been reported from only one ancient individual, from Amesbury Down in Wiltshire, England (Olalde et al., 2018). The predicted Y-chromosome haplogroup of the Low Hauxley Beaker individual, R1b1a1a2, has previously been found in Bell Beakers from Poland (Olalde et al., 2018), making both mitochondrial and Y-chromosome lineages of the Low Hauxley individual well established lineages within the Bell Beakers in Europe.

3.4.3 Bell Beaker ancestry

Similar to the Bronze Age individuals from Orkney (Chapter 4), the Bronze Age individual from Low Hauxley clustered closest with European Late Neolithic/Bronze Age individuals (Figure 3.3). However, admixture analysis showed that, although the highest proportions of ancestry were comparable to Late Neolithic/Bronze Age Europeans, he also had a small portion of shared ancestry with modern Near Eastern/North Africans. This 'African' component has also been found in modern Near Eastern and southern European populations, such as, for example, Spain and Sicily, but also to a certain extent in Neolithic and Bronze Age individuals from the Levant (Figure 3.4). North African ancestry has been shown to be highest in southwestern Europe with decreasing proportion towards the northern latitudes, and the sharpest difference appearing between Iberia and France (Botigué et al., 2013). However, this admixture has been estimated to be much more recent, dating to the Roman Empire and subsequent Arab migrations (Moorjani et al., 2011), and has not been observed in any European Bronze Age individuals analysed to date.

Based on suggested Bell Beaker migrations to Britain (Olalde et al., 2018), it is unlikely that the North African component in the Low Hauxley individual derived from Levantine or Near Eastern ancestry. Genetic analysis of Iberian Bronze Age cattle has shown that African and Iberian cultures must have been linked, as mitochondrial genomes of African cattle have been found in Iberian Bronze Age cattle (Anderung et al., 2005), suggesting interbreeding and cultural exchange. An extensive study on the genetic history of humans in Iberia found that a Copper Age individual, excavated in a Bell Beaker context at Camino de las Yeseras (San Fernando de Henares, Madrid, Spain), clustered with modern and ancient North Africans (Olalde et al. in review), and the authors suggested that the individual was a North African migrant. The association of Iberian and North African cultures during the Copper and Bronze Age has further been confirmed by analysis of a Bronze Age individual from Loma del Puerco (Chiclana de la Frontera, Cádiz), who carried 25% North African ancestry. The genetic similarity and shared association to the Bell Beaker culture between the reported individuals from Iberia (Olalde et al. in review) and the Bronze Age individual from Low Hauxley, England, suggests long-distance migrations of Bronze Age individuals. The North African component of the Low Hauxley individual suggests an ancestry-link to North Africa through Iberia, and supports the cultural connection between

Iberia and Britain during the Bronze Age, if low resolution artefacts can be ruled out by further sequencing.

Chapter 4

The Bronze Age and Iron Age in Orkney

4.1 Introduction

A Bronze Age cemetery was uncovered during excavations on the Links of Noltland (LoN), Westray, Orkney (Figure 4.1). The cemetery contained both cremation and inhumation burials, with the inhumations arranged to the north and west of a central cremation deposit. Two paired Bronze Age structures appeared to be the only boundaries, with formal cemetery boundaries missing. Two burial types are typically found in Orkney: flat cist cemeteries associated with mounds, and artificial mounds with cists inside (Moore and Wilson, 1995). However, the Bronze Age cemetery on the Links of Noltland does not fit into either of these categories. No mound could be found in relation to the cemetery, but it is possible that this might be due to severe erosion in the area. Considering the position of the Noltland cemetery to the paired Bronze Age structures, and the possible field systems to the north of the site, the funerary area appears to have had close associations with agricultural complexes (as discussed by Ovrevik 1985).

Twenty five articulated and twenty six disarticulated skeletons, as well as thirty six cremation deposits, were discovered. The articulated human remains could be aged accurately. Most women and all children were buried with grave goods, as was common practice during the Bronze Age, particularly in Ireland (Woddell 1990). Children were buried in stone-lined cists, while the majority of the adult inhumations were buried in simple sand-cut graves. Multiple burials appeared to be a common feature of this cemetery, with at least three identified multiple burials. The cremations were buried in simple sand-dug pits. At other sites in Bronze Age Orkney, multiple burials began to be replaced by single cist burials during the later Bronze Age, which

were then replaced by cremations. At Noltland, however, it appears from radiocarbon dates that inhumations and cremations occurred at the same time, suggesting that both rituals were of equal importance here. 25 of the excavated individuals were sampled for genome-wide analysis.

FIGURE 4.1: Map of the island of Westray, Orkney. The green circle indicates the position of the Bronze Age excavation site at the Links of Noltland, while the red circle indicates the position of the Iron Age excavation site at Knowe of Skea.

Additional to the Bronze Age cemetery on Westray, an Iron Age burial site was excavated at Knowe of Skea (KoS). The site of Knowe of Skea encompassed burials and material from the Neolithic to the Early Medieval era, such as a monumental stone building, and several buildings dating to the Bronze and Iron Age. The incredible number of individuals (>100) dating to the Iron Age within this site indicates an exceptional and unlikely domestic function of the cemetery, especially as over 60 individuals were neonates (Armit et al., 2007), and the cemetery is the largest yet discovered in Scotland (Moore and Wilson, unpublished). Three disarticulated inhumations of an adolescent, a middle aged adult and an older adult from Knowe of Skea were sampled for genetic analysis.

Uniparental markers have been used to analyse kinship among ancient multiple burials (Haak et al., 2008). Other studies have used mitochondrial HVS analysis and nuclear short tandem repeats (STRs) on ancient human remains to analyse kin relationships; for example, between individuals from a villa in Pompeii (Di Bernardo et al., 2009), bodies from sarcophaghi (Deguilloux

et al., 2014), Mongolian noble burials (Cui et al., 2015), or among Bronze Age pit burials (Palomo-Díez et al., 2018). However, STRs are generally difficult to type in ancient remains, and uniparental markers can only exclude certain direct relationships, as, even among unrelated individuals, most of the mitochondrial and Y-chromosome haplogroups found are relatively common (Kuhn et al., 2018), especially within Europe. As uniparental markers can not be used to infer any direct degree of kinship, genome-wide data is nowadays beginning to be used to identify individuals and their kin relationships (Kuhn et al., 2018). Tools for kinship analysis of ancient remains, such as the recently published READ (Kuhn et al., 2018), now allow for first- and second-degree kin analysis on low coverage whole-genome sequence data. READ assumes pseudohaploid data and performs a normalisation using an estimate for the pairwise distance of unrelated individuals to help overcome biases potentially arising from e.g. SNP ascertainment of general population diversity. Pair-wise distances are calculated between individuals and the given normalised P0 score, and standard errors denoted as Z_upper and Z_lower are used to assess the kinship classification. However, the results need to be interpreted with care, as the chance of false positive classifications is increased as the number of SNP loci decreases. Uniparental markers and archaeological context information should be used to facilitate the interpretation of the results.
The genetic analysis of 25 articulated inhumations of the Links of Noltland cemetery and three adult individuals from the Iron Age mass burial site at the Knowe of Skea cemetery aimed to identify possible family structures in multiple burials and across the two cemeteries using uniparental markers and kinship analysis. It was further envisaged that nuclear data might give insight into possible migration patterns to Orkney during the Bronze Age, and how/whether this persisted into the Iron Age.

4.2 Materials and Methods

Overall, 25 samples from the Bronze Age cemetery at Links of Noltland, consisting of 16 petrous bones and 9 teeth, were processed. All of the samples were part of the main cemetery and buried close to one another. Five of the individuals derived from a single grave that included multiple inhumations: inhumation numbers 9275 (1620-1450 cal. BC), 9302 (1499-1386 cal. BC), 9295 (1623-1458 cal. BC), 9291G (1610-1440 cal. BC) and 9304. Two other inhumations, 9414P and 9414S, also derived from the same grave. Of the remaining

individuals, four had been dated: 9244 (1520-1410 cal. BC), 9280 (1750-1530 cal. BC), 9053 (1630-1460 cal. BC) and 9290 (1610-1420 cal. BC).

Three individuals from the Iron Age cemetery at Knowe of Skea were sampled for their petrous bones. Of these, individual 4045 was dated to 1AD to 220 cal. AD. The sampling procedure and NGS library preparation was as described in Chapter 2. Samples LON 9293 and BNKS 4038 were dual-indexed for 100bp single-end sequencing on a HiSeq2500 (NBAF Liverpool, UK), while all other samples were single-indexed for 100bp paired-end sequencing on a HiSeq4000 (Macrogen, South Korea). Bioinformatic processing followed all steps as described in Chapter 2. Variants in linkage disequilibrium were filtered using the –indep-pairwise option in PLINK v0.67 with the parameters 200, 25 and 0.4. ADMIXTURE was run for ancestral population numbers from K=2 to K=14, with cross-validation enabled (–cv flag), on a merged dataset including the here presented samples together with the ancient and modern data of Lazaridis et al. (2016) and Olalde et al. (2018).

4.3 Results

Out of the 25 samples from the Links of Noltland, the library preparation of one sample (9303, decidious molar) failed and, therefore, the sample was excluded from sequencing. The library preparation of sample 9404 failed and it was thus excluded from any further analysis. All other 23 samples were analysed as described in Chapter 2.

4.3.1 Sequencing results

The endogenous DNA content of the samples ranged from 3.08 to 66.46% (Table 4.2). Whole genome coverage ranged from 0.0014x to 0.1293x, while the coverage of the mitochondrial genome ranged from 0.3328x to 51.2858x. The four libraries sequenced for KD006 (KD006.1, KD006.2, KD006.3 and KD006.4) had read counts of 5,968,323, 12,920,228, 6,786,040, and 1,078,610, the range of read counts is given in Table 4.2. The endogenous content of the four libraries sequenced for KD006 was 18.67%, 17.05%, 18.27%, and 16.82% respectively, and so its overall endogenous content is shown as a range in Table 4.2.

All three samples from Knowe of Skea passed the library preparation stage and were sequenced successfully. Their endogenous DNA contents ranged from 16.32 to 46.28%. The read count and endogenous content for KD004 are given as a range (Table 4.3, as a total of four single-end libraries were produced (KD004.1, KD004.2, KD004.3 and KD004.4), resulting in 28.34%, 29.43%, 28.58% and 28.18% endogenous content, and 7,670,025, 10,642,858, 26,376,756, and 22,201,481 reads, respectively. Whole genome coverage ranged from 0.0799x to 0.1100x, whilst mitochondrial genome coverage ranged from 4.8221x to 46.3234x. The duplication rate was <0.8% for all samples from both sites (see Tables 4.2 and 4.3).

TABLE 4.2: Sequencing results from 23 Bronze Age Links of Noltland samples and three Iron Age Knowe of Skea samples, from Westray, Orkney. Endogenous content for KD004 and KD006 is given as a range as explained in the text. 'SNPs' denotes the number of SNPs called with the published datasets as reference panel.

4.3.2 Genetic sex determination

Of the individuals whose sex could be determined using the Skoglund script, seven individuals were assigned as female, six as male and three as consistent with XY but not with XX (Table 4.4). For the remaining seven individuals whose genetic sex could not be determined using this method, karyotype plots were prepared and the X-chromosome percentage calculated (see Appendix E for details). This resulted in the determination of two males, three females and the sex of two individuals could not be assigned, due to low coverage.

4.3.3 Mitochondrial genome analysis

In the overall dataset, the main haplogroups observed were H, U5, T2 and K1. Two individuals had such a low mitochondrial genome coverage (KD051 and KD053) that no haplotype could be assigned. Five individuals were identified as belonging to haplogroup H39 (KD047-50 and KD065), while four other individuals were assigned to other subclades of the major European haplogroup H, namely H1n1 (KD057 and KD060), H58a (KD063), and H+195 (KD067). KD006, KD046 and KD066 belonged to haplogroup T2a1b1a, KD059 and KD064 to T2b21, KD045 and KD55 to J1c2a, and KD044 and KD062 to U5b2a3. One individual each was identified to belong to haplogroups K1a29a (KD052), K1a3a (KD058) and K1c2 (KD061).
The two males from Knowe of Skea belonged to the same mitochondrial haplogroup, H1b (KD004 and KD043), and had Y-chromosome haplogroups R1b1a1a2 and R1b1a1a2a1a2c1a2, respectively. The third individual (KD042), a woman, had mitochondrial haplogroup U5a1b1a. The complete mutation lists of each individual can be found in Appendix F.

4.3.4 Y-chromosome analysis

The results of the Y-chromosome analysis are summarised in Table 4.4. The complete lists of derived predictive markers per individual can be found in Appendix G.

TABLE 4.4: Osteological age estimate, genetic sex and identified uniparental markers are given. Bolded genetic sex indicates assignment based on Skoglund score. Ages with "?" are based on size of petrous bone only.

4.3.5 Kin relationship estimation

4.3.5.1 Links of Noltland

The kinship estimation with READ indicated that most individuals were first or second-degree related. The majority of the five individuals buried together in one grave (sample numbers KD047, KD049, KD050, KD058, KD065, see Table 4.1) were estimated to be first-degree related. The estimated degrees of kinship are shown in Table 4.5. The likely relationship between these individuals is shown schematically in Figure 4.2, as determined from the information shown in the comparison square (Table 4.6).

TABLE 4.5: Estimated genetic kin relationships of the Links of Noltland individuals. Higher and lower class of genetic difference (Z_upper and Z_lower) are given as standard errors from the normalised mean *P*0 score.

PairIndividuals	Relationship	Z_upper	Z_lower

4.3.5.2 Knowe of Skea

The only kin relationship that was identified among the Iron Age KoS samples was that the middle-aged adult woman (KD042) and the older adult man (KD043) are likely second-degree related (Table 4.7).

TABLE 4.7: Estimated genetic kin relationships of the Knowe of Skea individuals. Higher and lower class of genetic difference (Z_upper and Z_lower) are given as standard errors from the normalised mean *P*0 score.

Sample pair	Relationship	Z_upper	Z_lower
KD042+KD043	Second-degree	1.02717578217	-6.75304406054
KD042+KD004	Unrelated	NA	-13.42318498
KD043+KD004	Unrelated	NA	-113.803369616

4.3.6 Principal component analysis

Samples that had more than 10,000 SNPs in common with the published modern and ancient dataset (Lazaridis et al., 2016) were used for principal component analysis. Figure 4.3 shows that the Bronze Age individuals from Links of Noltland cluster closest together with the European Late Neolithic/Bronze Age individuals.

4.3.7 ADMIXTURE analysis

Samples with less than 10,000 SNPs were excluded from this analysis. The best value of *K* (lowest CV error; see Chapter 2 and Appendix H for details) generated for this ADMIXTURE analysis was *K*=12 (Figure 4.4).

4.4 Discussion

4.4.1 Genome coverage

Two samples from the Bronze Age cemetery at Links of Noltland were excluded from the analysis due to failures in the library preparation and sequencing stages. All remaining 23 samples were successfully sequenced, although to a very low coverage of less than 0.1x on average. Surprisingly, 20 of them had endogenous contents of over 10%, seven of which were above 40%. All three samples from the Iron Age cemetery at Knowe of Skea had endogenous contents over 10% and were sequenced successfully.
Due to the low coverage of the LoN Bronze Age samples, the genetic sex of

FIGURE 4.3: Principal component analysis (PCA) of the Links of Noltland (LON) and Knowe of Skea (KOS) samples merged with ancient European and Near Eastern populations (Lazaridis et al., 2016).

only 16 individuals could be determined using the Skoglund script (Skoglund et al., 2013). Using karyotype plots and X-chromosome percentages (Skoglund et al., 2015), it was possible to assign genetic sex to a further five of the otherwise undetermined individuals. Therefore, there were 10 females and 11 males (including the three individuals that were consistent with XY but not XX). The genetic sex of two individuals could not be assigned using either method as the coverage was too low, and the Skoglund score was inconclusive (Appendix E).

4.4.2 Estimated kin relationship

Based on the radiocarbon dates from the site, the skeletons were likely interred contemporaneously. This is especially interesting in the case of the boat-shaped grave complex containing 17 articulated and disarticulated individuals. Six of these were analysed genetically in this study (Figure 4.2), and five were identified as having a first-degree relationship. This supports the archaeological interpretation that the boat-shaped grave complex contained family-based burials. The two individuals 9414P (KD052) and 9414S (KD053) that were buried together in another grave did not produce enough

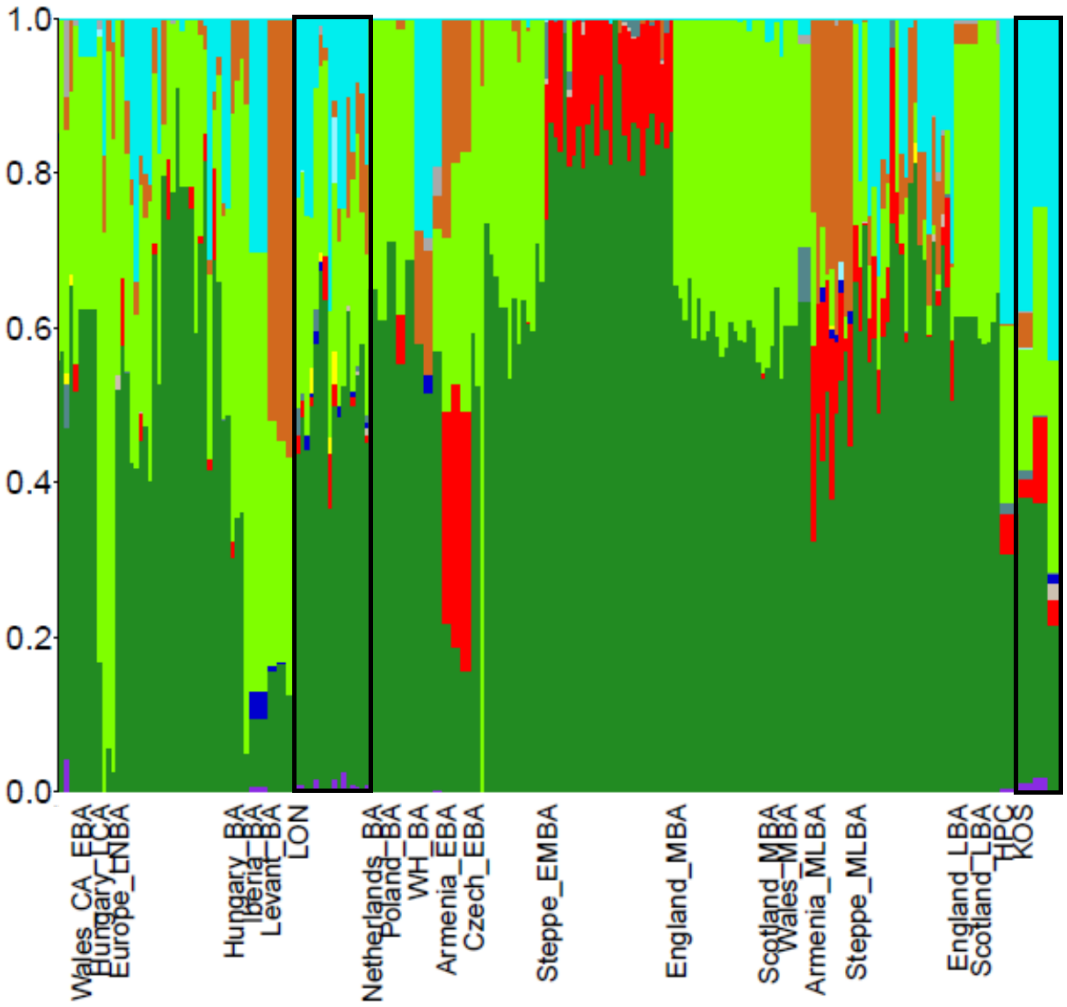

FIGURE 4.4: ADMIXTURE plot of the Bronze Age and Iron Age samples from Orkney together with ancient European and Near Eastern individuals from the same time period from Lazaridis et al. (2016) and Olalde et al. (2018). Abbreviations used: E: Early, M: Middle, L: Late, CA: Copper Age, BA: Bronze Age, LON: Links of Noltland, WH: West Heslerton, HPC: High Pasture Cave, KOS: Knowe of Skea.

variants to estimate any degree of kinship, and the coverage of KD053 was even too low to determine the mitochondrial haplogroup. It was, therefore, not possible to assign even a maternal relationship to these individuals.

Individuals buried in the boat-shaped grave complex and a few individuals buried in close proximity to it were identified as second-degree kin (see Figure 4.2). The adult male in burial 9374 (KD057) was found to be second-degree related to the infant male KD061 in burial 9326, as well as to the infant female KD062 in burial 9290. All three belong to very different

mitochondrial haplogroups, namely H1n1, K1c2 and U5b2a3 respectively. The Y-chromosome coverage of the adult male was too low to predict a Y-chromosome haplogroup, and so it was not possible to identify whether the adult male KD057 and the infant male KD061 were related through the paternal line. Based on the burials being contemporaneous, and the age of the individuals (KD057 was an old man, whilst the two related individuals, KD061 and KD062, were foetuses or infants), it is possible that KD061 may have been their grandfather or uncle.

The infant female KD062 was one of the individuals buried inside the boat-shaped grave complex, being also second-degree related to both the possibly juvenile male KD049 in burial 9275I and the adult male KD058 in burial 9295. She could have been the niece of KD049 and the granddaughter of KD058. Individuals KD058 and KD049 were first-degree related and most likely father and son, but, unfortunately, analysis of their Y-chromosome haplogroups was not possible due to low coverage. KD049 shared mitochondrial haplogroup H39 with the juvenile female KD050 in burial 9275C and the infant female KD065 in burial 9291G. All three were estimated to be first-degree related to each other, which suggests that they were siblings. The degree of kinship between adult male KD058, to KD050 and KD065, was determined as second-degree, which is contrary to the previously described scenario of KD058 being the father of all of them and not just KD049. However, it is possible that the degree of kin relationship was misclassified as second-degree rather than first-degree due to low coverage.

Within the boat-shaped grave, KD058 was first-degree related to the older adult male KD047 and they share mitochondrial haplogroup H39. Based on the age difference between them (KD058 was 26-35 years old, while KD047 was over 46), it seems most likely that KD047 was the father of KD058. This fits nicely with the second-degree kinship between KD047 and the three children KD049, KD050, and KD065, who were likely his grandchildren. Two further individuals that were buried outside the grave complex were identified as being second-degree related to individuals within the boat-shaped grave complex. An adult male KD045 was second-degree related to both males KD047 and KD058. Based on the age differences of the individuals, KD047 may have been the father of KD058 and the grandfather of KD045. KD058 would have then been the uncle of KD045 with his sister being the mother of KD045. The old adult male KD047 was also determined to be second-degree related to another individual from outside the grave complex, male KD059. Neither the age nor the Y-chromosome of KD059 is unknown,

so it is not possible to identify which of the two individuals would be the grandfather/uncle of the other, but there is a kin relationship.

4.4.3 Patrilocality

Overall, there appears to be patrilocality within the cemetery as, with the exception of the siblings and their grandfather belonging to mitochondrial haplogroup H39, no connection based on the female line of descent could be observed. All adult individuals that showed degrees of kinship were males. Samples KD046, KD048, KD051, KD052, KD053, KD059, and KD066 produced less than 10,000 SNPs and were, therefore, not suitable for READ analysis to estimate the degree of kinship. However, the analysis of all individuals within the Bronze Age cemetery based on their mitochondrial haplogroups indicated shared maternal lineages. Individuals KD006, KD046 and KD066 shared mitochondrial haplogroup T2a1b1a. The adult female KD044 shared haplogroup U5b2a3 with the female foetus KD062, which possibly makes it her child or grandchild. The young adult male KD045 shares the haplogroup J1c2a with the adult female KD055. The two adult males KD057 and KD060 share haplogroup H1n1, and male KD059 and neonate male KD064 both belong to haplogroup T2b21. The sharing of mitochondrial haplogroups suggests a shared maternal lineage, which is supported by the general finding that individuals within this cemetery were closely related. Similarly, shared Y-chromosome lineages indicated shared paternal lines of descent. Generally, the Y-chromosome coverage was very low and a low number of predictive markers was retrieved for most males, which made it impossible to determine the haplogroup more precisely than to haplogroup I for the majority. However, KD006, KD045 and KD064 had a higher number of derived predictive markers, and it was possible to identify that they shared Y-chromosome haplogroup I2a1b. Based on their individual ages at death, KD006 was possibly the senior relative.

4.4.4 Iron Age individuals from the Knowe of Skea

Mitochondrial genome analysis of the three Iron Age individuals from Knowe of Skea showed that the two male individuals were likely related through the maternal line, as they both belonged to haplogroup H1b. Although, their predicted Y-chromosome assignments showed that they both belonged to the same major Y-chromosome haplogroup R1b, their haplotypes were different, thus excluding a kinship through the paternal line. The predicted

Y-chromosome haplogroup R1b1a1a2a1a2c1a2 of the adolescent (KD004) is more derived than the predicted Y-chromosome haplogroup R1b1a1a2 of the older adult (KD043). Additional kinship analysis revealed an estimated second-degree relationship between the woman (KD042) and the older man (KD043). As the middle-aged adult woman belongs to a very different mitochondrial haplogroup than the two men, namely U5a1b1a, a maternal line of descent can be excluded. Therefore, the second-degree kin relationship suggests a grandfather-granddaughter relationship or an uncle-niece relationship, although it can't be excluded that they were half-siblings, sharing the same father.

4.4.5 Conclusions

In general, it appears that both the Bronze Age and Iron Age cemeteries on Westray, Orkney, represented familial use as, in both cases, most of the analysed individuals at each site were closely related to each other. However, it should be noted that the number of individuals from the Iron Age cemetery (n = 3) may not be representative of that time period, and the identified kin relationships might be an exception, especially since the vast majority of the individuals at Knowe of Skea were infants. Further genetic analysis of the remaining individuals would give information about the degree of kinship at the site as a whole, and allow for a more direct comparison to the Bronze Age cemetery at Links of Noltland.

PCA and ADMIXTURE analyses showed that the Bronze Age individuals from the Links of Noltland, as well as the Iron Age individuals from Knowe of Skea, showed very similar patterns to Late Neolithic/Bronze Age individuals from Europe. This striking similarity between the Bronze Age and Iron Age on Westray is highly suggestive of population continuity over at least 2,000 years.

Chapter 5

An Iron Age burial at the High Pasture Cave, Isle of Skye

5.1 Abstract

Human remains from the Iron Age in Atlantic Scotland are rare, which makes the assemblage of an adult female and numerous foetal bones at High Pasture Cave, on the Isle of Skye, particularly noteworthy. Archaeological evidence suggests that the female had been deposited as an articulated skeleton, as the cave entrance was blocked off, possibly as part of a 'closing deposit'. Particularly intriguing is the deposition of disarticulated remains from a perinate and a foetus close to the adult female. This intentional burial suggests that the female might have been the mother of both of the children. Shotgun genome sequencing was used in order to analyse the mitochondrial genomes of all three individuals, in order to investigate their relationships. The results revealed that, while the female could be the mother of the foetus, the perinate was not her child.

5.2 Introduction

High Pasture Cave (Uamh an Ard Achadh) is situated in the Parish of Strath on the Isle of Skye (Figure 5.1).
Stonework found in the surface trench was associated with a series of entrance arrangements, which led down a stone stairwell into the cave, whose system provides direct access to an underground stream. The passage had been deliberately blocked with boulders and sediments (Birch et al., 2013), with deposition of human remains from three individuals into the top of the blockage (Figure 5.2), along with remains of a foetal pig and perinatal dog.

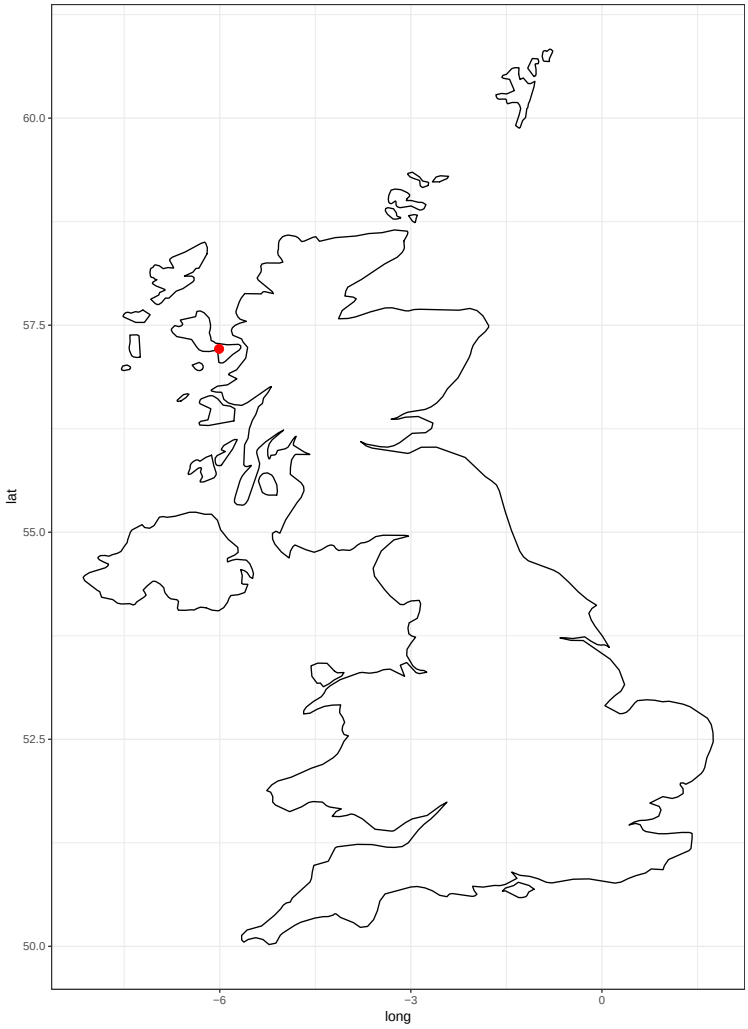

FIGURE 5.1: The location of the High Pasture Cave within the British Isles.

The remains found at this site display distinct ritual aspects, such as the burial of animals after butchery, and the presence of both disarticulated human remains and complete human inhumations, including foetal and infant burials (Birch et al., 2013; Livarda et al., 2017). The unusually high amount of pig remains also suggests a feasting deposit (Livarda et al., 2017).
The human remains consisted of an adult female, aged between 25-40 years, found together with two infants: one perinate that died during the last month of foetal development or during the first two weeks of life, and one foetus that died between 12 and 26 weeks of gestation. Further down the stairwell, the proximal half of a left tibia relating to a second perinate was found. These deposits might have moved down through the voids, away from the main burial environment (Birch et al., 2013) or else have been buried at a different time. Additional fragments of human bone, teeth and partially burnt

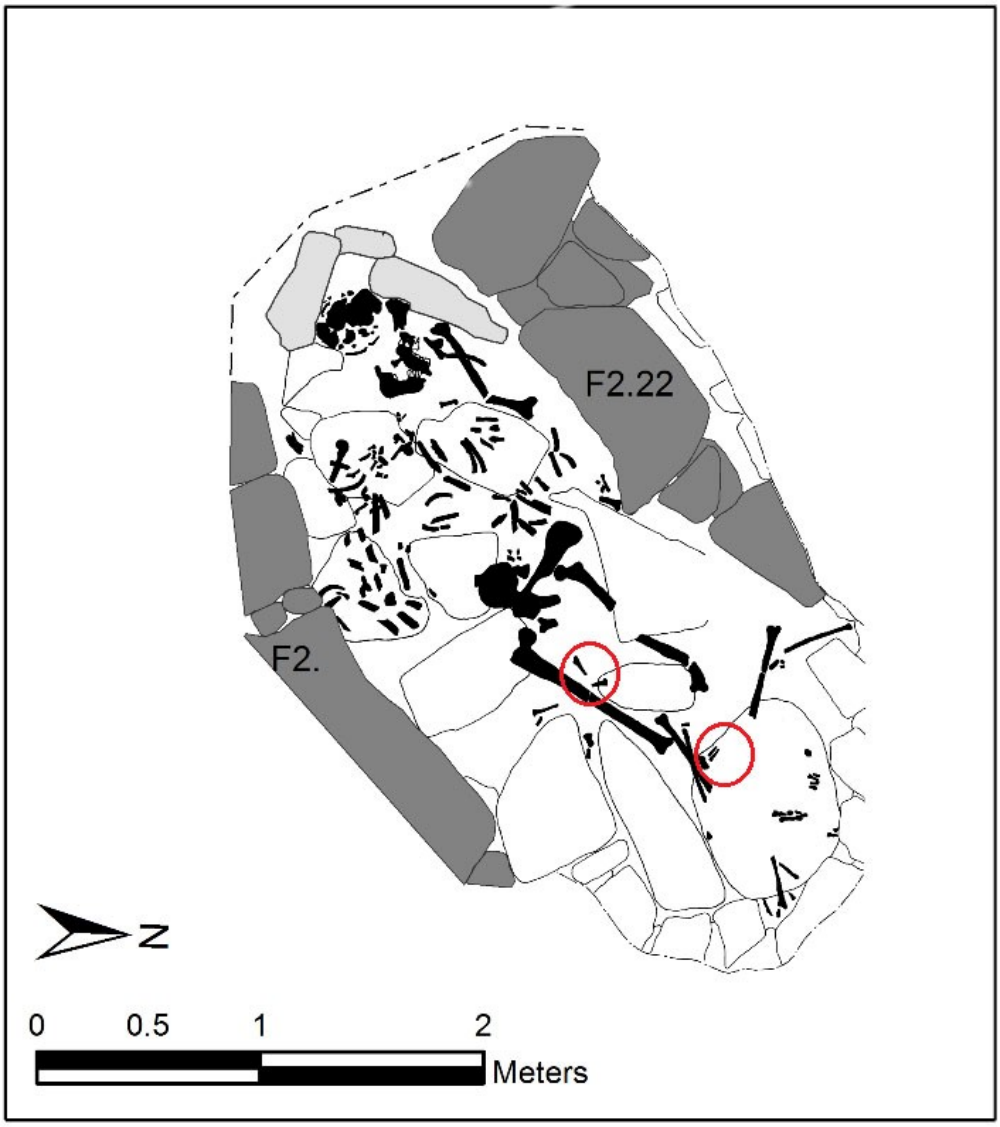

FIGURE 5.2: Schematic of the stairwell backfill with burials in the High Pasture Cave. The red circles indicate the position of the foetal bones.

human skull fragments were also discovered within the cave system, as well as outside the cave entrance (Birch et al., 2013). The woman appears to have been buried intact under the stones and this has led some to surmise that she may have been deliberately crushed to death (Armit, in press).

The wider environment surrounding the site revealed a diverse archaeological landscape of monuments and sites relating to prehistoric and historic periods, including a number of funerary monuments, and hut-circles combined with well-preserved field systems (Birch et al., 2013). Radiocarbon dates of samples from different layers within the cave, and from the complex deposits

outside the cave entrance, indicate periodic activity at High Pasture Cave from the 13th century *cal*. BC to *cal*. AD 1st century. This, and the diversity of small finds, indicates a complex occupation history with several phases of intense activity during the Iron Age (Birch et al., 2013). The archaeological material found in the cave indicates a typical domestic assemblage comprising bone, stone and iron tools, ceramics and residues of metalworking. Furthermore, a well-preserved faunal assemblage has been recovered, including animal and fish bones, shellfish and charred plant remains. Among the animal bones, a high percentage could be assigned to domesticated pig, which display evidence of unusual butchery practices, such as deliberate division of skeletons into left and right parts and unusual cut-marks across several pig ribs (Drews, 2005). The human remains of the High Pasture Cave adult female yielded a calibrated radiocarbon date of *cal*. AD 28-230 (2σ; SUERC-14946), which corresponds to the Iron Age in this region. The infant remains were radiocarbon dated to *cal*. AD 63-219 (SUERC-66371) for the foetus and *cal*. AD 76-228 (SUERC-66372) for the perinate (Figure 5.3).

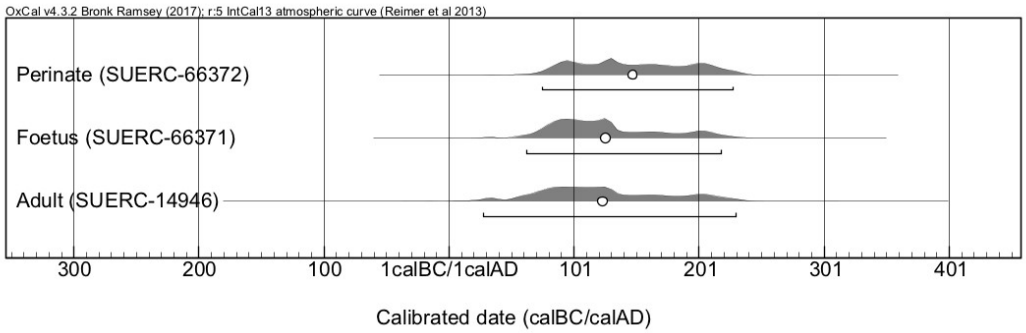

FIGURE 5.3: Calibrated radiocarbon dates for the analysed human remains of the High Pasture Cave stairwell.

During the Iron Age, unusual and specific burials for women, foetuses and infants were rather common (Finlay, 2000; Armit et al., 2007). The general archaeological interpretation has been that the women must have died in childbirth and were thus buried together with their foetuses. In order to validate this assumption the genetic relationship of the adult female to the foetus and the perinate was analysed.

5.3 Materials and Methods

5.3.1 Sampling and DNA extraction

A petrous bone from the female adult, and infant bone fragments from the perinate (ischium) and the foetus (scapula), were sampled for genetic analysis. The sampling was carried out at the Ancient DNA Facility at the University of Huddersfield under dedicated clean-room conditions. Laboratory researchers wore full body suits, hairnets, gloves and face masks throughout the drilling, extraction and library preparation processes. All tools and surfaces were constantly cleaned with LookOut® DNA Erase (SIGMA Life Sciences), as well as with bleach, ethanol and long exposures to UV light.
The bone surfaces were decontaminated by UV radiation for 30 minutes on each side, followed by cleaning with 5 µm aluminium oxide powder using a compressed air abrasive system. For the adult sample, the densest part of the petrous bone (Pinhasi et al., 2015) was excised using a circular saw. Bone powder was obtained by crushing this excised petrous portion, and the complete bone fragments from the two infants, in a MixerMill (Retsch MM400). DNA was extracted from ∼150mg of the petrous powder and 50-100mg of each infant bone, following the protocol by Yang et al. (1998) with modifications by MacHugh et al. (2000). Blank controls were included throughout the extractions, library preparation and amplification reactions to monitor for possible modern DNA contamination.

5.3.2 Library preparation and sequencing

Next-generation sequencing libraries were constructed from DNA extracts using the method described in Meyer et al. (2010), with modifications outlined in Gamba et al. (2014) and Martiniano et al. (2014). Briefly, the changes were as follows: T4 DNA polymerase buffer (Thermo Scientific) was used instead of Tango buffer in the blunt-end repair step and the *Bst* polymerase activity was heat-inactivated by incubating the libraries for 20 minutes at 80°C. Indexing amplifications were set up using Accuprime *Pfx* Supermix (Life Technology), primer IS4 (0.2µM), a specific indexing primer (0.2µM) and 3 µl of sample library, with a total reaction volume of 25 µl. All DNA purification steps were performed using the QIAQuick MinElute purification kit (Qiagen) following the manufacturer's protocol, with the modification of adding 0.05% Tween 20 (Fisher BioReagents) to the elution buffer.

Single-end libraries were prepared for both of the infant samples. Amplification was undertaken using the following thermal cycling conditions: 5 minutes at 95°C; 11 cycles of 15 seconds at 95°C, 30 seconds at 60°C and 30 seconds at 68°C; with a final extension step of 5 minutes at 68°C. The resulting amplification products were purified using the QIAQuick MinElute purification kit (Qiagen) as described above.
As the individual was part of an earlier study, four dual-index libraries (Kircher et al., 2012) were prepared for the adult sample. Amplification was set up using AmpliTaq Gold (5U/µl), Thermopol reaction buffer (10x), dNTPs (10mM each), both indexing primers (10µM each) and 10µl DNA sample library. The following thermal cycling steps were used for amplification: 12 minutes at 95°C; 10 cycles of 20 seconds at 95°C, 30 seconds at 60°C, and 40 seconds at 72°C; with a final extension step of 5 minutes at 72°C. We purified the amplification product using the QIAQuick MinElute PCR purification kit as described above. For the second amplification round, Accuprime *Pfx* Supermix (Life Technology) was used, together with primers IS5 (10µM), IS6 (10µM) and 2.5 µl of sample library. The amplification was carried out under the following thermal cycling conditions: 30 seconds at 98°C; 10 cycles of 20 seconds at 98°C, 30 seconds at 60°C, and 40 seconds at 72°C; with a final extension of 5 minutes at 72°C. The resulting amplification product was purified as described above.
All amplification reactions were quantified using a Qubit 3.0 Fluorometer, and additionally the libraries were quantified using an Agilent 2100 Bioanalyzer High Sensitivity DNA kit prior to pooling them equimolarly for next-generation sequencing (NGS) purposes. For the adult, four dual-indexed libraries were sent for 100-bp (base-pair) single-end sequencing on a HiSeq2500 (NBAF Liverpool, United Kingdom), whereas the infant remains were assigned one single-indexed library each, which were sent for 100-bp paired-end sequencing on a HiSeq4000 (Macrogen, South Korea).

5.3.3 Bioinformatic analysis

5.3.3.1 Single-end sequencing analysis

The NGS reads were trimmed and aligned to the human mitochondrial genome (rCRS, NC_012920.1; Andrews et al. 1999) and the human reference genome (UCSC hg19). The reads were trimmed using cutadapt (v.1.13; Martin 2011), allowing a minimum overlap of 1 bp between read and adapter (adapter sequence: AGATCGGAAGAGCACACGTCTGAACTCCAGTCAC), discarding

reads shorter than 30 bp. BWA aln (v.0.7.12-r1039; Li et al. 2009a) was used to map reads to both the rCRS and hg19, filtering by base quality 15, and disabling seed length, as recommended for ancient DNA data (Schubert et al., 2012), with a maximum edit distance of 0.01 and maximum number of gap opens set to 2. Samtools version 1.3 was used to sort and filter reads, and to remove PCR duplicates, and DNA damage patterns were assessed using mapDamage 2.0 (Jónsson et al., 2013) and bamdamage (Malaspinas et al., 2014). Picard tools (v.2.18, `http://broadinstitute.github.io/picard`) was used to add read groups to the sequencing reads aligned to hg19, and the sequencing quality was assessed using FastQC (version 0.11.5; Andrews 2016) and qualimap (v.2.2.1; Okonechnikov et al. 2016). Samtools mpileup and bcftools (v.1.3) were used to create a consensus FASTQ file of the alignment to the rCRS, and SEQTK (v.1.2-r102-dirty) was used to convert the FASTQ file into FASTA format. Schmutzi (Renaud et al., 2015) was used to detect possible modern mitochondrial contamination, and mitochondrial haplotypes were assigned using Haplogrep 2 (Weissensteiner et al., 2016).

5.3.3.2 Paired-end sequencing analysis

The only difference in the treatment of the paired-end reads compared to single-end reads was the use of AdapterRemoval (v.2.1.7; Schubert et al. 2016), which trimmed the adapters from the read pairs and merged the reads.

5.3.3.3 Mitochondrial haplotype calling

The consensus sequence of the mitochondrial genome was created using samtools mpileup and bcftools; additionally GATK (v.3.7) was used to call the variants against the rCRS for the two infant samples. As the coverage of the foetus and perinate mtDNA genomes was very low, this approach enabled identification of as many polymorphisms from the mitochondrial genome as possible. All other bioinformatic steps were the same for both read types.

5.3.3.4 Phylogenetic tree reconstruction

All available published data from complete mitochondrial genomes was used to reconstruct the phylogenetic tree of the determined haplogroup, as well as data generated as part of a larger British Isles study. MtPhyl v4.015 (Eltsov et

al. 2011; `https://sites.google.com/site/mtphyl/home`) was used to reconstruct the phylogeny, applying the discrete-character method maximum parsimony. The reconstructed tree was reviewed based on mtDNA PhyloTree build 17 (`http://www.phylotree.org/tree/index.htm`).

5.4 Results

DNA was successfully extracted and sequenced from all three samples. The endogenous DNA content of the adult, perinate and foetus was quite low, with 11.89%, 8.01% and 7.57%, respectively. The genome of the adult female was sequenced to a coverage of 0.276x, while her mitochondrial genome was sequenced to a coverage of 58.068x. For the two infants, the genome coverage was 0.014x for the perinate and 0.006x for the foetus, with mitochondrial genome coverages of 4.140x and 2.241x, respectively. Due to the low coverage of the genomes of the foetus and the perinate and the extremely low number of retrieved overlapping SNPs (<10,000), no additional autosomal analysis was possible.

5.4.1 Contamination estimates

Contamination estimates ranged from 0.165 to 0.185% for the adult female and 0 to 0.005% for both infants. No exogenous contamination was observed in extraction or library blanks, supporting the authenticity of the results, and there were no matches between the mitotypes from the three ancient samples and those of the researchers.

5.4.2 Genetic sex identification

The genetic sex was identified using the tool published by Skoglund et al. (2013). The osteological determination that the adult was female was supported by the genetic sex identification. No sex could be assigned for the two infants due to low genomic coverage.

5.4.3 Mitochondrial haplotype determination

The mitochondrial haplotypes of the individuals show that only one of the infants shares the same haplogroup as the adult female. Due to gaps and low coverage in the foetal mitochondrial genome, the haplotypes do not fully match. However, the female and the foetus both belong to haplogroup H7a1b

(Table 5.1), whereas the perinate was assigned to haplogroup J1c3 (Table 5.2). To securely determine mitochondrial haplotypes for the infants, two bioinformatic approaches (that is, GATK Variant Call versus calling the consensus sequence, as discussed in the methods section) were compared, and the same haplotypes were assigned using both methods. Table 5.1 shows the called mutations for the adult female and her putative child, the foetal individual. Mutations that are likely due to deamination, polymorphisms or 'unspecified' are highlighted in Table 5.3. A more thorough overview of the rationale behind every disregarded mutation can the found in Appendix J.1.

5.5 Discussion

5.5.1 Novel approach

This is the first time that complete ancient mitochondrial DNA (mtDNA) sequences from foetal-aged bone fragments have been reported. Previous studies have used PCR-based methods to determine the genetic sex of neonates (Faerman et al., 1998; Waldron et al., 1999; Irish et al., 2008), but no mitochondrial genomes or genome-wide data have been published to date.
Due to the low genome coverage retrieved from the infants, it was not possible to determine the molecular sex of either the perinate or the foetus, and no genome-wide analysis could be performed. It is possible that a PCR-based approach, such as in Palomo-Díez et al. (2018) might have succeeded, but the aim of this study was to investigate the relationship between the three individuals, and shot-gun sequencing promised the best approach to cover as much of the mitochondrial genome as possible. Based on previous sequencing results of ancient samples, it is known that the mitochondrial genome can be sequenced to high coverage as a byproduct of sequencing the entire genome, even if the nuclear genome sequencing is not covered well enough to allow for WGA. Sequencing the whole mitochondrial genome results in a much more detailed analysis of the haplotype than a PCR-based approach where typically only fragments of the non-coding region are amplified.

5.5.2 Iron Age burials of infants

The separation of infant burials from the rest of the population appears to have been widespread across the Iron Age and into the Romano-British period (Redfern et al., 2011). At some sites, this separation is thought to be a special treatment involving age-specific funerary rites (Millett et al., 2015), while at others it appears to be due to deposition without any ceremony (e.g. Saville et al. 1994; Finlay 2000; Armit et al. 2007). In the British Iron Age, women that died in childbirth, as well as foetuses and young infants, were given special burials, highlighting the importance of the link between woman and child (Millett et al., 2015). Human remains of infants or foetuses were often placed into cave systems, and the number and spread of cave burials during this period in Scotland is relatively high – especially given that burials from this period are generally not abundant (Saville et al., 1994). There is also evidence of infants being buried in unstable, abandoned buildings or disused settlement sites. For example, an excavation at the site of

Howe in Orkney revealed an Iron Age burial of an adult male, aged between 35 and 45 years, along with a perinate and an infant, all of whom had been placed within accumulated rubble in a midden in a disused yard (Armit et al., 2007). The bones showed gnaw marks, and their layout was interpreted as an informal burial; that is, they were deposited without ceremony (Armit et al., 2007). Another example is the Iron Age site at the Knowe of Skea, also in Orkney, where over one hundred, mainly infant, bodies were found deposited in domestic rubble contexts. Cremations and inhumations of adult women with foetal/neonatal remains in reused, separate burial areas are also known from Ireland (Finlay, 2000).

5.5.3 High Pasture Cave context

The context of the High Pasture Cave appears different to those described above, as a domestic setting is not indicated by any of the structural features (Livarda et al., 2017). The trauma evident on the female, and the lack of any wider tradition of inhumation in the region, has led to the suggestion that this burial was a deviant one, or even a sacrifice connected to the closure of the cave stairwell, rather than a ceremonial burial of a mother and her child (Armit, in press). The burial raises several questions, especially now that the genetic results show that only the foetus was likely to be the female's child, but not the perinate.

5.5.4 Maternal lineages

Mitochondrial genomes are used to trace the female line of descent, as they are passed on from mother to child without recombination. The only changes that occur over generations are naturally-occurring mutations, and these can be used for phylogenetic reconstructions over wide geographic areas and long timespans. The main defining mutations for haplogroup H7a1b can be found in both adult and foetus (bolded in Table 5.1); i.e. the transitions at positions 1719, 16261 and 1393 which define H7a, H7a1 and H7a1b, respectively. The read at the defining mutation for H7 at position 4793 shows the ancestral, instead of the derived, state in the foetus, and the majority of the mutations in this mitochondrial genome are most likely due to deamination (Dabney et al., 2013) or environmental factors, such as radiation and alkylation (Willerslev et al., 2005). These positions were, therefore, counted as being less significant when determining the haplogroup (Appendix J.1). Haplogroup H occurs at ∼44% of all British mtDNA lineages, but haplogroup H7

is a minor European subclade found at ∼1.6% in Britain, and its nested subclade H7a1b occurs at only ∼0.3% (Frequencies of H7a1b are given in Table 5.4, and additional information on haplogroup H7 can be found in Appendix C).

TABLE 5.4: Frequency table of H7a1b in Europe based on complete sequencing data and SNP capture data.

	Number of complete sequences	Frequency based on complete sequences in percent	Number of SNP capture based haplotypes	Frequency based on SNP capture in percent
England	1	11.1	4	22.2
Scotland	2	22.2	13	72.2
Ireland	-	-	1	5.5
Denmark	4	44.4	-	-
Finland	1	11.1	-	-
Sardinia	1	11.1	-	-

5.5.4.1 Haplogroup H7a1

In the database of extant whole-mitogenome lineages, H7 is commonly found in Mediterranean Europe, whereas H7a is more focused on north-western Europe (Britain, n = 10; Denmark, n = 16; Germany, n = 13), with some individuals in the central Mediterranean and others as far east as Finland and Russia (Behar et al., 2012a; Li et al., 2014; Raule et al., 2014; Olivieri et al., 2017; Dulias, 2019). Its major subclade, H7a1, dates to ∼6.4 ka based on maximum likelihood calculations. The earliest instance of H7 discovered so far is from the Early Neolithic *impressa* culture of Croatia, dating to ∼7.6 ka (Mathieson et al., 2018), while a Middle Neolithic individual from Hungary dates to ∼7.1 ka (Lipson et al., 2017). The earliest H7a1 individual known is from the Balkans Eneolithic Varna culture, dating to ∼6.6 ka. Various H7 lineages have also been seen from the Late Neolithic, through the Corded Ware and Bronze Age of central Europe (Mathieson et al., 2018; Olalde et al., 2018). The overall distribution pattern suggests that H7a lineages may have been dispersed north from the Mediterranean with the spread of the Neolithic. The subhaplogroup of H7a1b dates to ∼4.5 ka and is seen in modern-day Scotland (Dulias, 2019), England (Behar et al., 2012a) and Denmark (Behar et al., 2012a; Li et al., 2014; Raule et al., 2014), as well as Finland and Sardinia, but the individuals from High Pasture Cave are the earliest known H7 lineages from north-west Europe (Figure 5.4).

Given the geographic diversity and young age of H7a1b, it may have reached Britain more recently than the settlers carrying the Bell Beaker culture, when the genome-wide pattern of the British gene pool began to take on its modern form – possibly in the Bronze Age or in the Iron Age itself.

5.5.4.2 Haplogroup J1c

In contrast, the perinate belongs to haplogroup J1c (subclade J1c3). Haplogroup J1c is an almost entirely European subclade of haplogroup J, dates to ∼17 ka, and is the most frequent subclade of J, with J1c3 dating to ∼11.5 ka (Pala et al., 2012; Pereira et al., 2017). The mitochondrial genome of the perinate had better coverage than the foetus, and all of the defining positions of J1c3 subclades were covered. As none of the defining mutations of any of the J1c3 subclades could be observed, we can securely say that the mitogenome of this individual is basal to J1c3. Over 100 ancient J sequences have been published to date, of which >60% fall within J1c and are mainly found in the Neolithic and Bronze Age in Germany, the British Isles and Hungary (Gamba et al., 2014; King et al., 2014; Allentoft et al., 2015; Günther et al., 2015; Haak et al., 2015; Mathieson et al., 2015; Cassidy et al., 2016; Hofmanová et al., 2016; Lazaridis et al., 2016; Martiniano et al., 2016; Juras et al., 2017; Knipper et al., 2017; Lipson et al., 2017; Margaryan et al., 2017; Neparáczki et al., 2017; Saag et al., 2017; Schuenemann et al., 2017; Brace et al., 2018; Mathieson et al., 2018; Mittnik et al., 2018; Olalde et al., 2018). J1c has been present in the British Isles since the Early Neolithic (Olalde et al., 2018), although the earliest J1c3 individuals to date are both post-Beaker: a Chalcolithic/Early Bronze Age individual from Kent (Olalde et al., 2018) and one Roman individual from Yorkshire (Martiniano et al., 2016). The earliest J1c3 individual was found in Early Neolithic Spain (Haak et al., 2015), but it was present as far north and east as the Ukraine by 4.8 ka, prior to the spread of the Corded Ware (Mathieson et al., 2018). Thus, although the Iron Age lineage might be a survival from the earlier Neolithic in the British Isles, it could also potentially trace its ancestry to the rise of the Beaker culture on the continent, and its time of arrival in Britain is not clear.

5.6 Conclusions

The results of this study show that only one of the two infants buried alongside the adult female was possibly her child, whereas the perinate did not share the maternal lineage with her. This is an interesting find considering the common archaeological understanding of these type of female/foetus burials, where the children are assumed to be related to the women. So far archaeological interpretations of these burials have indicated either a mother-child relation or a midwife buried in the same place as foetuses and infants. In the case of the High Pasture Cave, where the pregnant woman was likely

crushed to death, archaeological questions still remain, such as why she was killed and why she was buried with a likely unrelated child? The most favoured explanation is that she was interred as part of a sacrificial closing burial. The genetic analysis showed that a general assumption of mother-child relations within such burials can be misleading and that genetic analysis can assist quite drastically the analysis and interpretation of archaeological contexts.

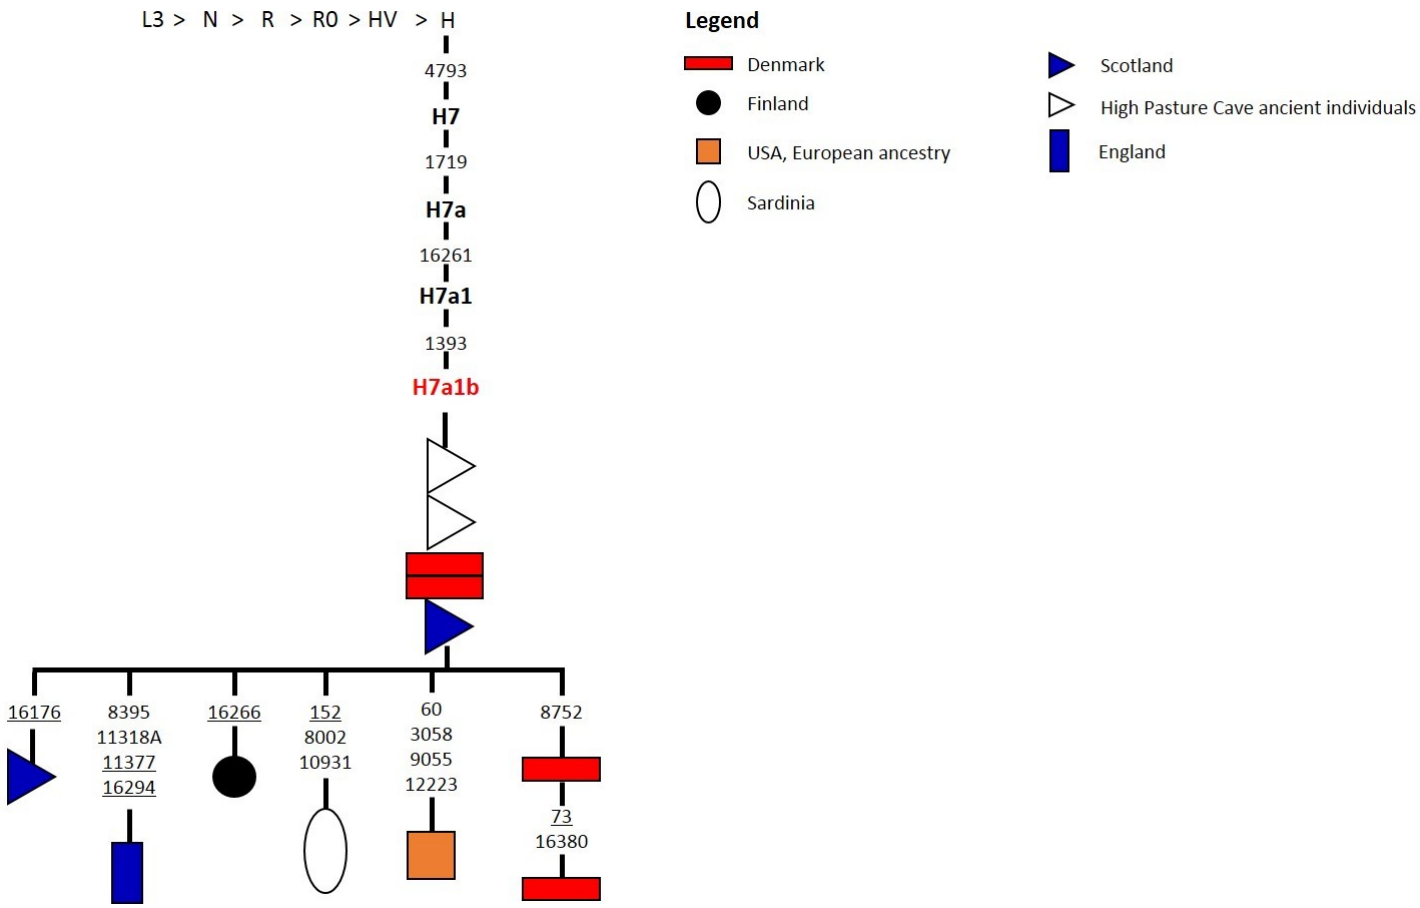

FIGURE 5.4: Schematic of the branch H7a1b of the mitochondrial DNA phylogenetic tree of haplogroup H7. The legend shows the origin of the samples. Recurrent mutations are underlined, transversions are indicated as postfixes. Scottish ancient samples from the High Pasture Cave are indicated as blank triangles.

Chapter 6

Rosemarkie Man - an unusual local or a foreigner in Pictish Scotland?

6.1 Introduction

Since 2006, the Rosemarkie Cave Project has been investigating the archaeology of 19 caves in the southeast of the Black Isle, Scotland (Figure 6.1). First results indicate that some caves were visited or occupied during the 7th-9th centuries AD. Further open-area excavations of this site uncovered iron-working activity and a *c.* 5th-7th century male inhumation burial.
Based on the archaeological layers, it is likely that the iron-working took place before or during the early medieval period and the cave continued to be used throughout the medieval and post-medieval periods (Birch et al., 2017). Radiocarbon dates of animal bones from across the site gave an overlapping time frame of 600-941 AD. Later investigations provided radiocarbon dates from archaeological sequences of worked bone and antler from the 2nd-3rd century AD. The male inhumation burial was found below a post-medieval cobbled floor and midden deposits in a dark alcove, and comprised the well-preserved remains of a young male (pers comm. Prof. Sue Black) who had suffered severe, multiple trauma to the head. The grave was unmarked, with stones weighting down the limbs, and butchered animal bones were placed over the position of the head (Birch et al., 2017). The burial is quite remarkable as its position, and the condition of the individual at the time of death, is unusual. The skeleton was aligned in a northwest-southeast position with the skull pointing to the southeast. The arms were by the side of the torso, while the lower limbs/feet were in a "cross-legged" position (Figure 6.2).
Forensic analysis showed that the individual was very healthy and of a robust build. He died due to multiple trauma wounds to his skull, caused by more than one weapon (Birch et al., 2017). A fragment of the left rib was taken for radiocarbon analysis and provided a date of *cal*. AD 430-631

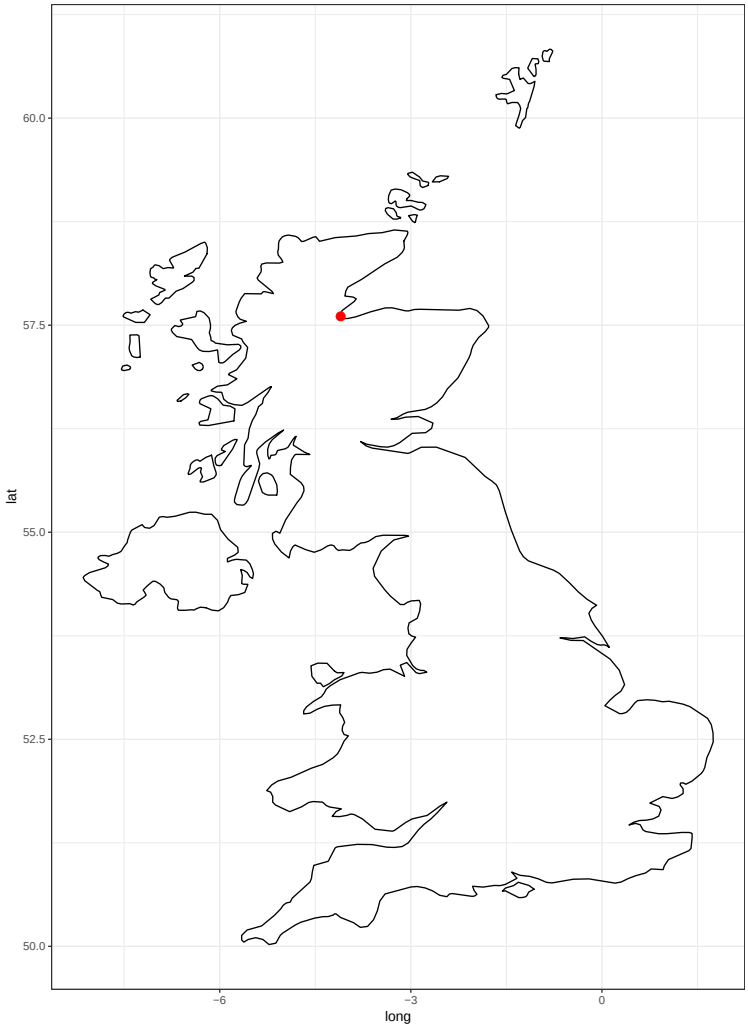

FIGURE 6.1: Location of the Rosemarkie Cave system within the British Isles (adapted from Birch et al. 2017).

(SUERC-70721). Strontium isotopic analysis gave a mean result of 0.70995 $^{87}Sr/^{86}Sr$ from two maxillary teeth, which fits with local values. Results of oxygen isotopic analysis are not available yet. Based on the unusual position and setting of the burial, it indicates a deliberate interment.

The stones that were placed on top of the body may represent an attempt to hold down the body after death, with the animal bones representing an offering, which may indicate a ritual act. The selection of the cave may have formed an important part of the burial process (Birch et al., 2017). Given the date range of the early 5th to 7th centuries, the burial could potentially represent Pictish, Viking, early Christian or other influencing factors, due to the many cultural influences and developments of that time in this region (Birch et al., 2017). Further to the forensic analysis of the burial, facial reconstruction has been undertaken (see Figure 6.3) (Birch et al., 2017).

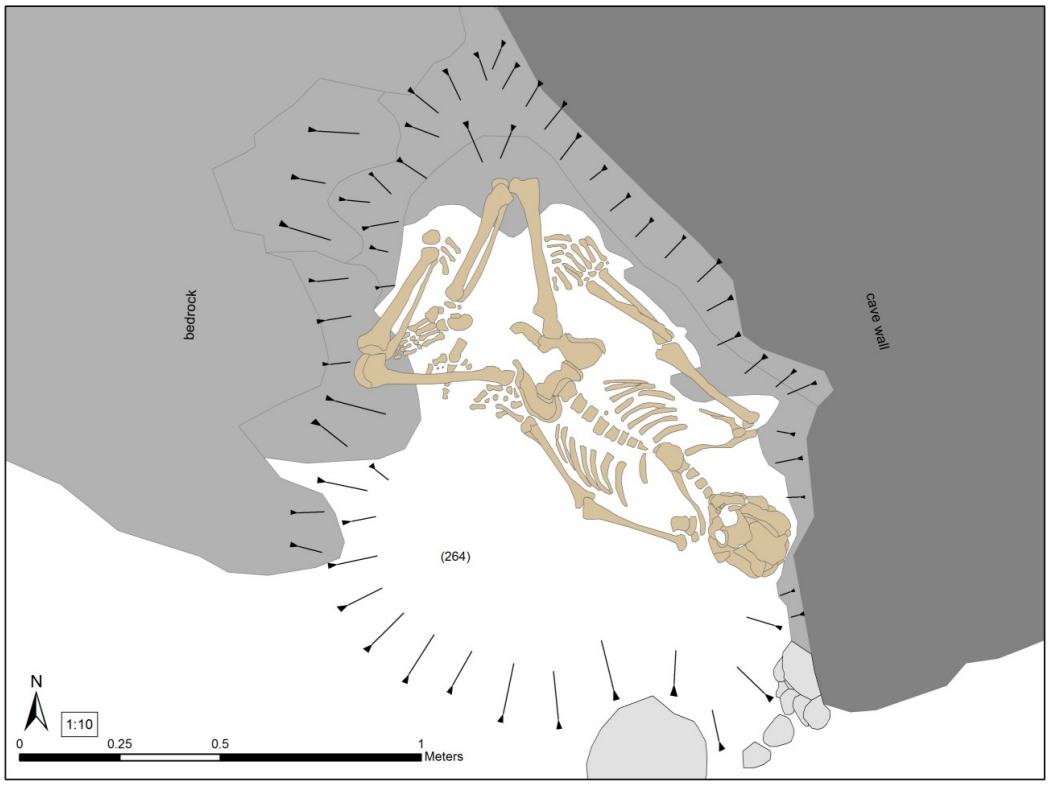

FIGURE 6.2: Schematic of the analysed inhumation after excavation (adapted from Birch et al. 2017).

6.2 Materials and Methods

6.2.1 Ancient sample processing

Ancient DNA sample processing was done at the Ancient DNA Facility of the University of Huddersfield (England) and the Ancient DNA lab, Smurfit Institute, Trinity College Dublin (Ireland), under dedicated clean-room conditions. The same protocol for sample processing and ancient DNA extraction was used in both labs.

6.2.2 Sampling and DNA extraction

The petrous bone of the Rosemarkie skull was detached from the intact cranium using a cutting saw attached to a hobby drill at the University of Huddersfield and shipped to the Ancient DNA lab at Trinity College Dublin (TCD), where the surface of the bone was decontaminated by UV radiation for 10 minutes on each side of each sample. The surface of the petrous was removed using a standard drill bit, followed by the excision of a piece of the densest petrous parts using a circular saw (Pinhasi et al., 2015). Bone

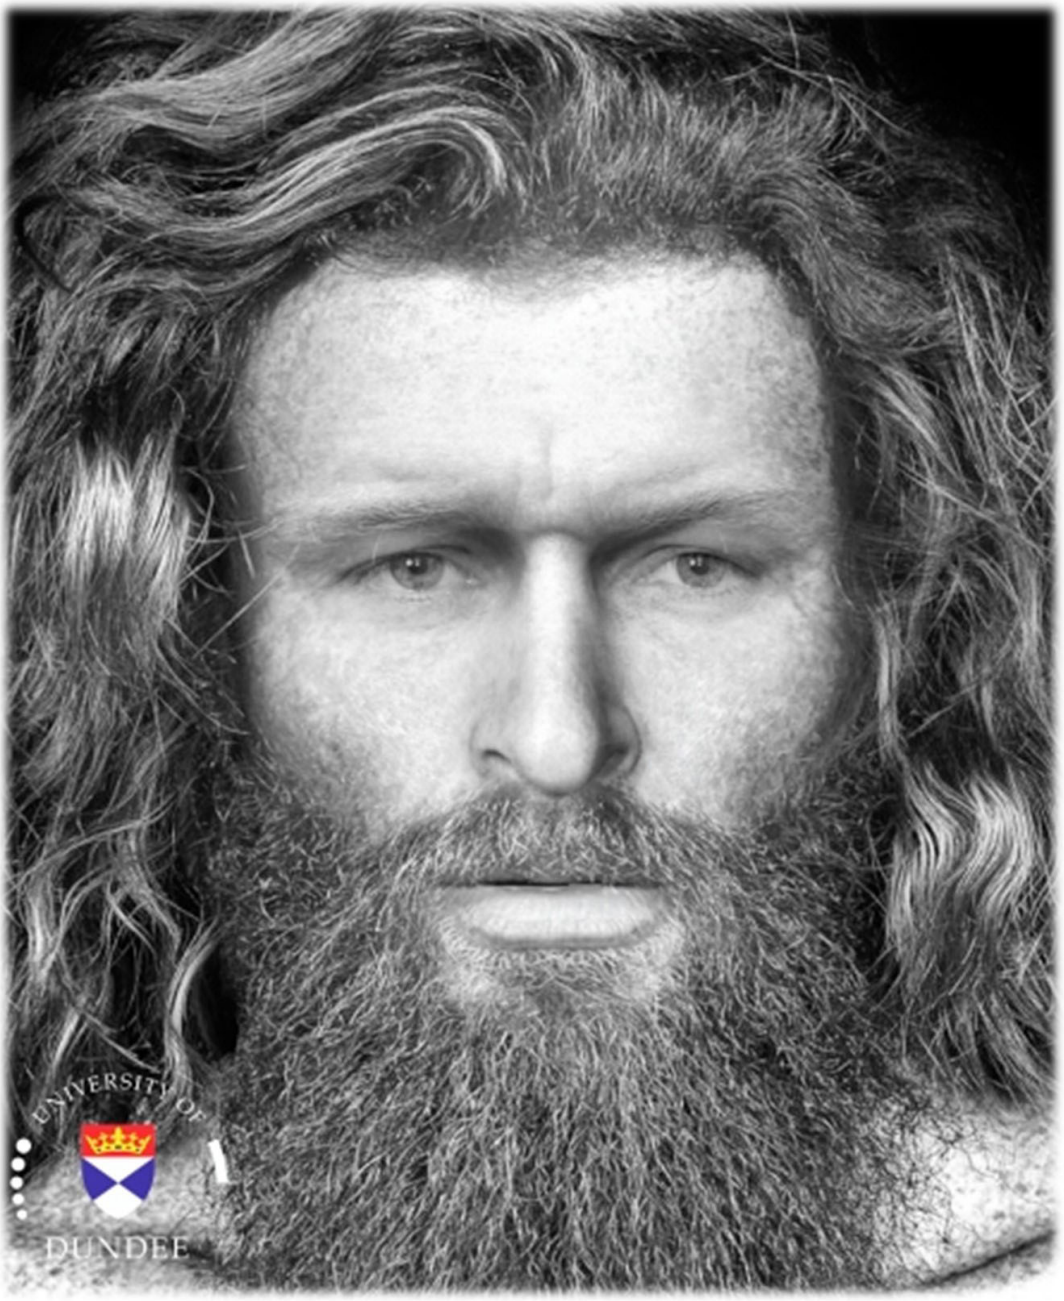

FIGURE 6.3: Facial reconstruction of the Rosemarkie individual (reproduced with permission of Prof. Dame S. Black).

powder was obtained by crushing the excised bone pieces with a Mixer-Mill (Retsch MM400). DNA was extracted from approximately 150 mg of the sample powder produced, following the protocol by Yang et al. (1998) with modifications by MacHugh et al. (2000). Blank controls were included throughout extractions to allow for quatification of contamination. Further sampling for bone powder was done following the exact same protocol at the Ancient DNA Facility of the University of Huddersfield.

6.2.3 Library preparation and sequencing

6.2.3.1 Library preparation

Library preparation followed the protocol described in Chapter 2. For the Rosemarkie sample one single-indexed library was prepared at TCD. Five further libraries were prepared at the University of Huddersfield. Three libraries were dual-indexed and two libraries were single-indexed. The same protocol was used in both labs, with the only difference being the single- and dual-indexing.
Amplification reactions performed at TCD were quantified using an Agilent 2200 TapeStation and pooled equimolarly. Amplification reactions performed at the University of Huddersfield were quantified using an Agilent 2100 Bioanalyzer High Sensitivity DNA kit and pooled equimolarly.

6.2.3.2 Sequencing

The NGS library prepared at TCD was sequenced in an Illumina HiSeq 2000 (single-index, 100 base pair, single-end sequencing; Macrogen, South Korea), library code KaD1. NGS libraries prepared at the University of Huddersfield were sequenced in an Illumina HiSeq 2000 (dual-index, 100 base pair, single-end sequencing; NBAF Liverpool, United Kingdom), library codes KD001.1, and KD001.2, and in an Illumina HiSeq 4000 (single-index, 100 base pair, paired-end sequencing; Macrogen, South Korea), library codes K23 and K34. Dual-indexing was due to requirements of NBAF Liverpool and single-end versus paired-end sequencing differed at Huddersfield between the two sequencing companies.

6.2.4 Data processing and read mapping

The NGS reads of libraries KaD1, KD001.1, and KD001.2 (all single-end sequenced) were trimmed using cutadapt version 1.13 (Martin, 2011), allowing a minimum overlap of 1 bp between read and adapter (adapter sequence: AGATCGGAAGAGCACACGTCTGAACTCCAGTCAC), and discarding reads shorter than 30 bp. The NGS reads of libraries K23 and K34 (paired-end sequenced) were trimmed using AdapterRemoval version 2.1.7 (Schubert et al., 2016), to remove adapters from read pairs, trim Ns, remove low quality bases from the reads and merge reads (`-trimns -trimqualities -collapse -adapter1` AGATCGGAAGAGCACACGTCTGAACTCCAGTCAC `-adapter2` AGATCGGAAGAGCGTCGTGTAGGGAAAGAGTGT). Alignments were run

per library as described in Chapter 2, with the additional step of merging the separate alignments at the bam stage with `samtools merge`. After merging, the sample ID was KD001. All further analyses, such as sexing, analysis of uniparental marker, PCA and ADMIXTURE were run as described in Chapter 2. For the genome-wide analysis the previously described adult individual from High Pasture Cave (Chapter 5) was included, as it dates to the same period and was found geographically close to the Rosemarkie individual.

6.3 Results

6.3.1 Sequencing results

Sequencing results are displayed in Tables 6.1 and 6.2. Information on the negative controls can be found in Appendix D.

TABLE 6.1: Sequencing results of all combined libraries sequenced of the Rosemarkie individual. 'SNPs' denotes the number of SNPs called with the published datasets as reference panel.

Sample ID	Read count	Endogenous content in %	Duplication rate in %	Genome coverage	SNPs
KD001	3,652,867-105,144,736	60.91-90.05	0.68	0.7519x	544,787
KD005	10,040,467-64,122,526	11.87-13.25	1.02	0.276x	223,914

TABLE 6.2: Read count and endogenous contents of KD001 and KD005 libraries. Indexing type indicates whether a library was single or dual indexed. Read type indicates single-end (SE) and paired-end (PE) sequencing.

Lab ID	Read count	Endogenous content in %	Indexing type	Read type
		KD001		
KaD1	22,461,152	87.48	single	SE
KD001.1	11,790,087	89.99	dual	PE

K23	77,619,946	60.91	single	PE
K34	105,144,736	83.28	single	PE
		KD005		
KD005.1	10,040,467	13.25	dual	PE
KD005.2	64,122,526	11.87	dual	PE
KD005.3	18,991,631	13.16	dual	PE
KD005.4	20,104,930	12.40	dual	PE

6.3.2 Mitochondrial contamination estimates

In order to detect possible modern mitochondrial contamination, schmutzi (Renaud et al., 2015) was used. Estimates of mitochondrial contamination ranged from 0.24-0.35%, showing very little modern mitochondrial contamination.

6.3.3 Genetic sex determination

To determine the sex of the analysed ancient sample, software published by Skoglund et al. (2013) was used, which calculates the ratio of reads aligning to the X and Y chromosome. The individual studied was determined as male, supporting the results of the osteological analysis.

6.3.4 Mitochondrial genome analysis

The haplotype of the presented ancient sample was determined aligning the sample sequence reads to the revised Cambridge Reference Sequence (rCRS; NC_012920.1; Andrews et al. (1999)) using BWA filtering (with -b and -q 30), and duplicate reads were removed. The mtDNA consensus sequence was called using Samtools mpileup, as in Jones et al. (2015), Cassidy et al. (2016), and Martiniano et al. (2016). Haplofind (Vianello et al. 2013) was used to identify haplogroup defining mutations and assign the haplogroup of the sample (Results in Table 6.3). The mtDNA coverage was estimated using samtools. The individual was found to have all the defining mutations of haplogroup J1b1a1a.

TABLE 6.3: Mitochondrial DNA haplogroup and mutations identified

Sample	Haplogroup	Average coverage	Polymorphisms
KD001	J1b1a1a	96.2727x	73G 263G 462T 489C 750G 1438G 2706G 3010A 4216C 4769G 7028T 8557A 8860G 10398G 11251G 11719A 12007A 13708A 13879C 14766T 15326G 15452A 16069T 16126C 16145A 16172C 16192T 16222T 16261T

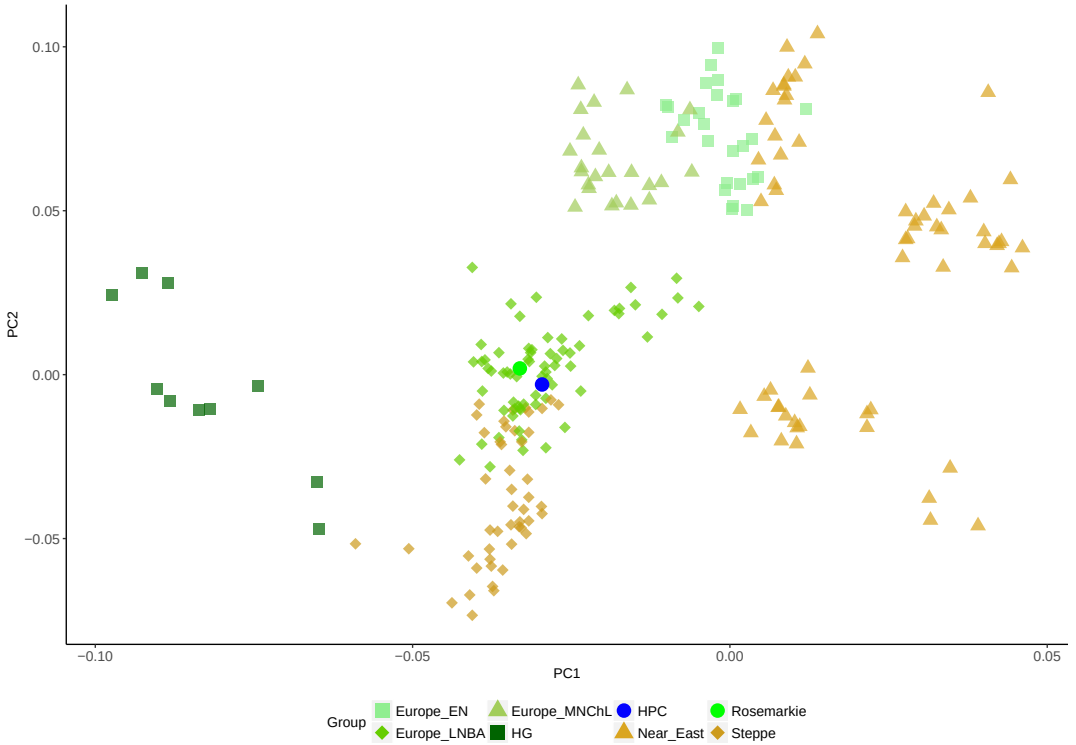

FIGURE 6.4: Principal component analysis of the Rosemarkie and High Pasture Cave individuals, with previously published ancient samples of Lazaridis et al. (2016) projected onto the first two principal components.

6.3.5 Y-chromosome analysis

The Y-chromosome analysis gave R1b1a1a2a1a as the predicted haplogroup with L151 and L11 being the most downstream predictive markers. For more details see Appendix G Table G.14.

6.3.6 Genome-wide analysis

For the genome-wide analysis, the Rosemarkie individual was analysed alongside the Pictish adult female from the High Pasture Cave, Isle of Skye (see Chapter 5 for more details), and the dataset of modern and ancient individuals used in Lazaridis et al. (2016). The individual from the High Pasture Cave had 223,914 overlapping SNPs with the published dataset.

6.3.6.1 Principal component analysis

The PCA of the two individuals from Rosemarkie and High Pasture Cave shows them plotting with the European Late Neolithic/Bronze Age samples (Figure 6.4).

6.3.6.2 ADMIXTURE

The ADMIXTURE plot is given in Figure 6.5. Further information on the ADMIXTURE analysis can be found in Appendix H. Both, the Rosemarkie Cave and High Pasture Cave, individuals appear most similar to the Iron Age individuals from Knowe of Skea, Orkney.

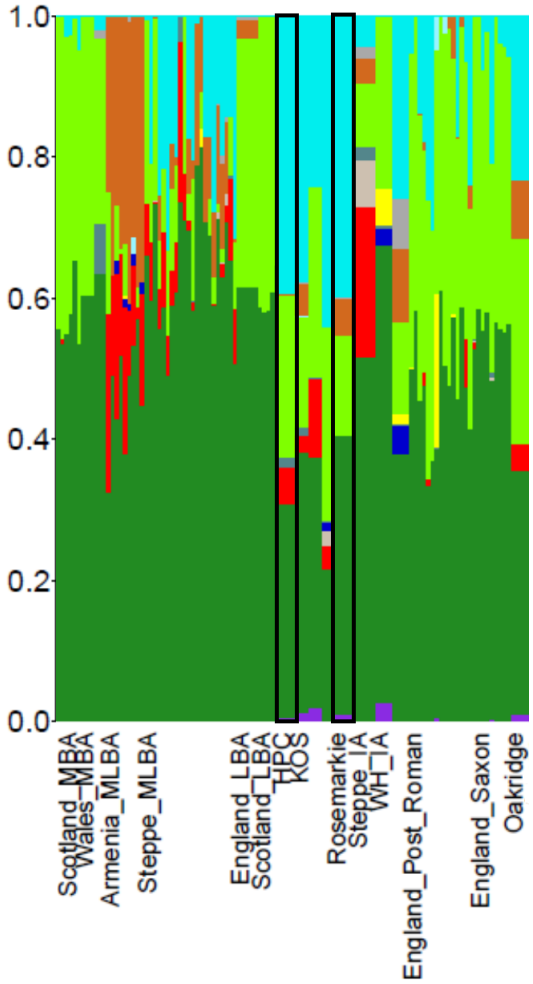

FIGURE 6.5: ADMIXTURE analysis of the Rosemarkie and High Pasture Cave individuals, with previously published ancient samples of Lazaridis et al. (2016) and Olalde et al. (2018) for K=12. Abbreviations used: E: Early, M: Middle, L: Late, BA: Bronze Age, IA: Iron Age, WH: West Heslerton, HPC: High Pasture Cave, KOS: Knowe of Skea.

6.4 Discussion

6.4.1 Genome coverage

The genome coverage of the Rosemarkie individual was >0.7% and allowed genome-wide analysis with published modern and ancient genomes, as well as a detailed analysis of his uniparental markers. The mitochondrial genome coverage was close to 100x and therefore, the complete mtDNA haplotype was recovered and the individual was securely determined to belong to haplogroup J1b1a1a, which is almost restricted to the British Isles (and Norway).

6.4.2 Maternal lineage

Mitochondrial haplogroup J originated in the Fertile Crescent of the Near East (Pala et al., 2012). Based on its geographic distribution haplogroup J likely diversified in the Near East around the time of the LGM. Subhaplogroups of J are nowadays present in both Near East and Europe, with J1b, J1c and J2 being mainly Near Eastern and J1c solely European. J1b is predominantly Near Eastern, except for J1b1a, which is considered European (Pala et al., 2012). J lineages are thought to have entered Europe during the Late Glacial period, prior to the Neolithic in Europe. The maternal lineage of the Rosemarkie individual is, therefore, one of the older European haplogroups. Another analysed contemporaneous male from Milla Skerra at Sandwick on Unst, Shetland Islands, was determined to belong to subhaplogroup J1b1a, which is basal to the clade the Rosemarkie individual sits in. Unfortunately, the autosomal genome coverage of this individual was very low and no Y-chromosome haplogroup could be predicted and no genome-wide analysis was possible for the same reason (for supplementary information on the Shetland individual please refer to Appendix K).

6.4.3 Paternal lineage

Within Europe, typically >50% of men belong to Y-chromosome haplogroup R. The most common subclade within R in Europe is R1, which shows a distinctive geographic distribution, where R1a is essentially eastern and R1b western European (Myres et al., 2011). The majority of western European men belong to Y-chromosome haplogroup R1b, as it is the most common male lineage cluster in this region, with highest frequencies of almost 100% in Ireland and the Basque country. Several studies have linked R1b to the

spread of the Corded Ware culture (Silva et al., 2019). During the Late Neolithic and Bronze Age, common Y-chromosome lineages in early European farmers almost disappear and were largely replaced by R1b in western Europe (Haak et al., 2015).

6.4.4 Genome-wide analysis

As the Rosemarkie Cave, and the High Pasture Cave (discussed in Chapter 5) are both in Scotland, and excavated individuals in both caves belong to the Scottish Pictish period and the Iron Age, their genomic data was analysed alongside each other. The PCA of the autosomal data showed that both the Rosemarkie and the High Pasture Cave individuals cluster closest with Late Neolithic/Bronze Age individuals from Europe (Figure 6.4). ADMIXTURE analysis showed a more nuanced picture (Figure 6.5). Both individuals appear most similar to the Iron Age individuals from Knowe of Skea, Orkney. A comparison of the genomes of the Rosemarkie and High Pasture Cave individuals with the genome of the Milla Skerra individual would be very interesting and might shed light on the population movements and admixture events across Scotland and the Scottish Isles, but further sequencing of the Milla Skerra human is required. The availability of more Iron Age individuals from the British Isles would further facilitate this analysis.
Because the burial of the Rosemarkie man was peculiar, it raised several questions, such as whether the man was a Scottish local or a foreigner. Genome-wide analysis showed that the individual was a local and that his terrible death cannot be explained by him being a foreigner.

Chapter 7

The Post-Roman cemetery at Worth Matravers, Dorset

7.1 Introduction

The archaeological site of Worth Matravers is located in Dorset (Figure 7.1). The area around Worth Matravers shows human occupation from the Neolithic/Early Bronze Age period to the late 8th century AD (Ladle, 2018b). One of the sites dating to the post-Roman period is a cemetery that was used for about 100 years during the 7th and early 8th centuries AD.

FIGURE 7.1: The location of Worth Matravers within the British Isles.

The graves in the cemetery are oriented in an east-west direction (Figure 7.2), organised in rows, and they generally lack grave goods, which is consistent with post-Roman/Early Medieval cemeteries in the west of Britain. The rare

find of a limestone anchor used as a head rest in one grave has been recognised in burials from the Romano-British and Early Medieval periods (Ladle, 2018a). The cemetery held 26 individuals in 21 graves, of which 16 were analysed genetically. There is a possibility of close kinship and marital relationships, which are likely reflected by the occurring double and triple burials. The excavated graves are of seven different types, varying from simple earth-cut to complex cist-type, and all except the earth-cut type had varying amounts of limestone incorporated. The differences in burial types may reflect social structures, such as familial bonds or social status. Genetic analysis of the 16 individuals was undertaken to identify possible kin relationships, and dietary stable isotope data was analysed to help identify social differences within the cemetery.

7.2 Materials and Methods

Teeth from 16 individuals excavated in the post-Roman cemetery in Worth Matravers were processed for DNA extraction and dietary stable isotope analysis as described in Chapter 2. DNA extracts were shipped to collaborator David Reich (Harvard Medical School) for enriched 1.2M SNP and mitogenome capture and data processing (Olalde et al., 2018). Kinship analysis was carried out using READ (Relationship Estimation from Ancient DNA) (Kuhn et al., 2018). Genetic sex determination was undertaken using the script by Skoglund et al. (2013), and Y-chromosome haplogroup determination using Yleaf (Ralf et al., 2018). In order to compare the newly generated ancient dataset to modern human populations, known informative SNP positions of the publicly available Lazaridis et al. (2016) dataset were used and SNPs were filtered as described previously (Mathieson et al., 2018; Olalde et al., 2018). Principal Component Analysis was run using smartpca of the EIGENSOFT package (Patterson et al., 2006; Price et al., 2006) and plotted with R version 3.4.4 (R Core Team, 2018). A combined dataset of the post-Roman genotypes, together with the reference panel, was run using ADMIXTURE (Alexander et al., 2009). Calibrated radiocarbon dates in cal. AD from six burials were calibrated using the IntCal13 atmospheric curve (Reimer et al., 2013) in OxCal v.4.3.2 (Ramsey, 2017). Calibrated radiocarbon dates were provided by our collaborator Bob Kenyon (Kruz, 2018). Stable isotope analysis followed as described in Chapter 2.

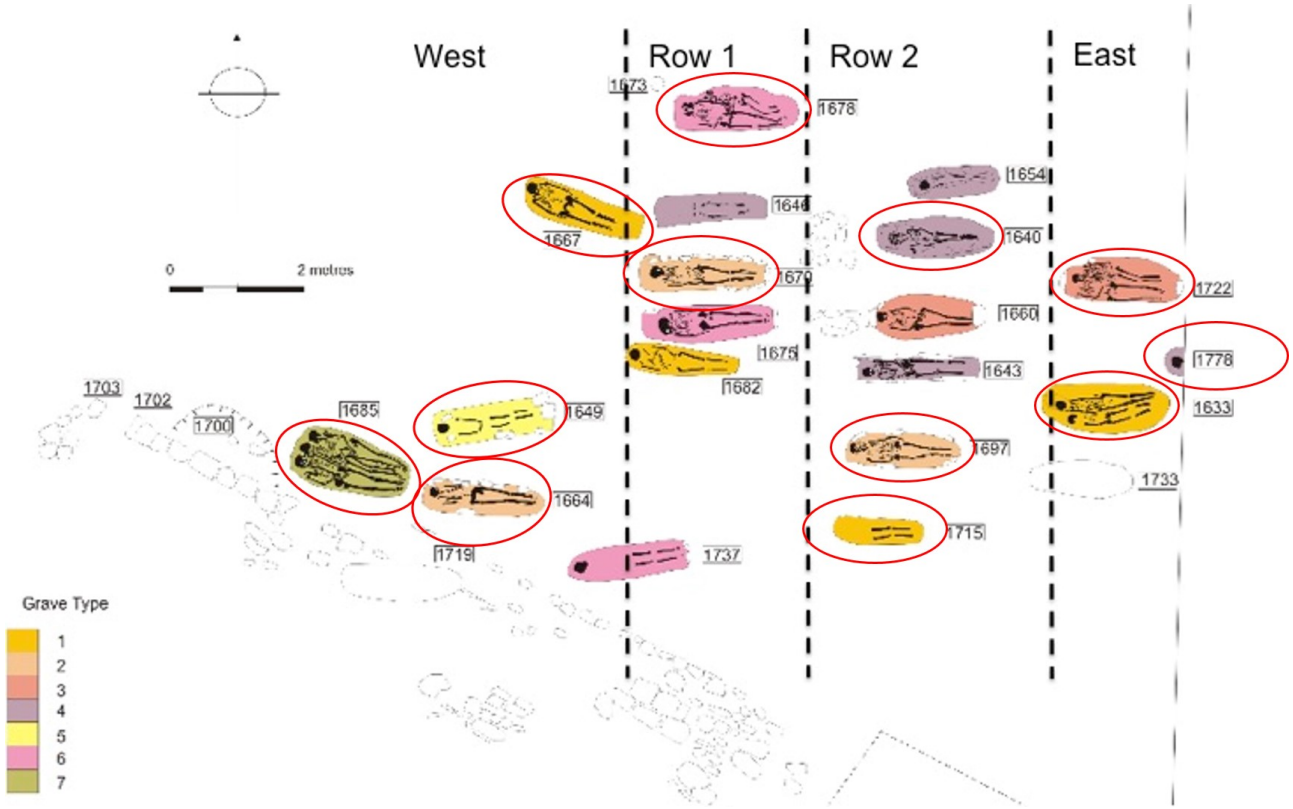

FIGURE 7.2: Schematic of the post-Roman at cemetery Worth Matravers in Dorset, England. Grave types: 1 - plain earth-cut; 2 - rubble lining or kerb alongside; 3 - stone lumps/slabs at head and foot position; 4 - cist-type with split limestone slab walls and occasional lids; 5 - stone lumps at either side of head and irregular arrangement of slabs/rubble at the foot end of the grave; 6 - one vertical stone at either head or foot; 7 - horizontal slabs on top of grave. Dotted lines indicate the distinction between the different rows as West, Row 1, Row 2 and East. Red circles indicate sampled graves. Figure modified from Ladle (2018b).

7.3 Results

All DNA samples passed the quality control and were sequenced successfully. The endogenous content ranged from 0.001% to 0.8%, the coverage ranged from 0.006x to 0.3x, and the overall SNP hits on autosomes ranged from 7,359 to 261,880 (Table 7.1).

TABLE 7.1: Sequencing results of the 1,240K SNP capture of the individuals from the post-Roman cemetery at Worth Matravers. Coverage, number of SNP hits on autosomes and the number of Y-chromosome markers are given. Letters A, B and C indicate different individuals within one burial. 'SNPs' denotes the number of SNPs called with the published datasets as reference panel.

7.3.1 Age range of the cemetery

Radiocarbon dates were obtained from six burials across the cemetery (data provided by Bob Kenyon; analysis carried out by Anthony Kruz at the Scottish Universities Environmental Research Centre (SUERC)). They show that the cemetery was in use for about 100 years. Three different periods were

classified: early phase (∼500 AD), intermediate phase (∼630 AD) and late phase (∼680 AD). One date each falls into the early and late phases, whilst four dates fall within the intermediate phase. The distribution of the phases across the cemetery is shown in Figure 7.3 A. An overview of the radiocarbon dates is given in Table 7.2.

TABLE 7.2: Radiocarbon dates of selected graves from the post-Roman cemetery at Worth Matravers.

Grave ID	Dating code	Uncal. dates in bp	cal. AD (95.4%)	Classified time period
1677	SUERC-61177	1340 ± 31	644 – 766	late phase
1633	SUERC-61178	1393 ± 31	600 – 673	intermediate phase
1640	SUERC-61179	1396 ± 31	599 – 671	intermediate phase
1678	SUERC-61180	1413 ± 31	583 – 665	intermediate phase
1685	SUERC-61182	1425 ± 31	575 – 660	intermediate phase
1697	SUERC-61181	1547 ± 29	424 – 575	early phase

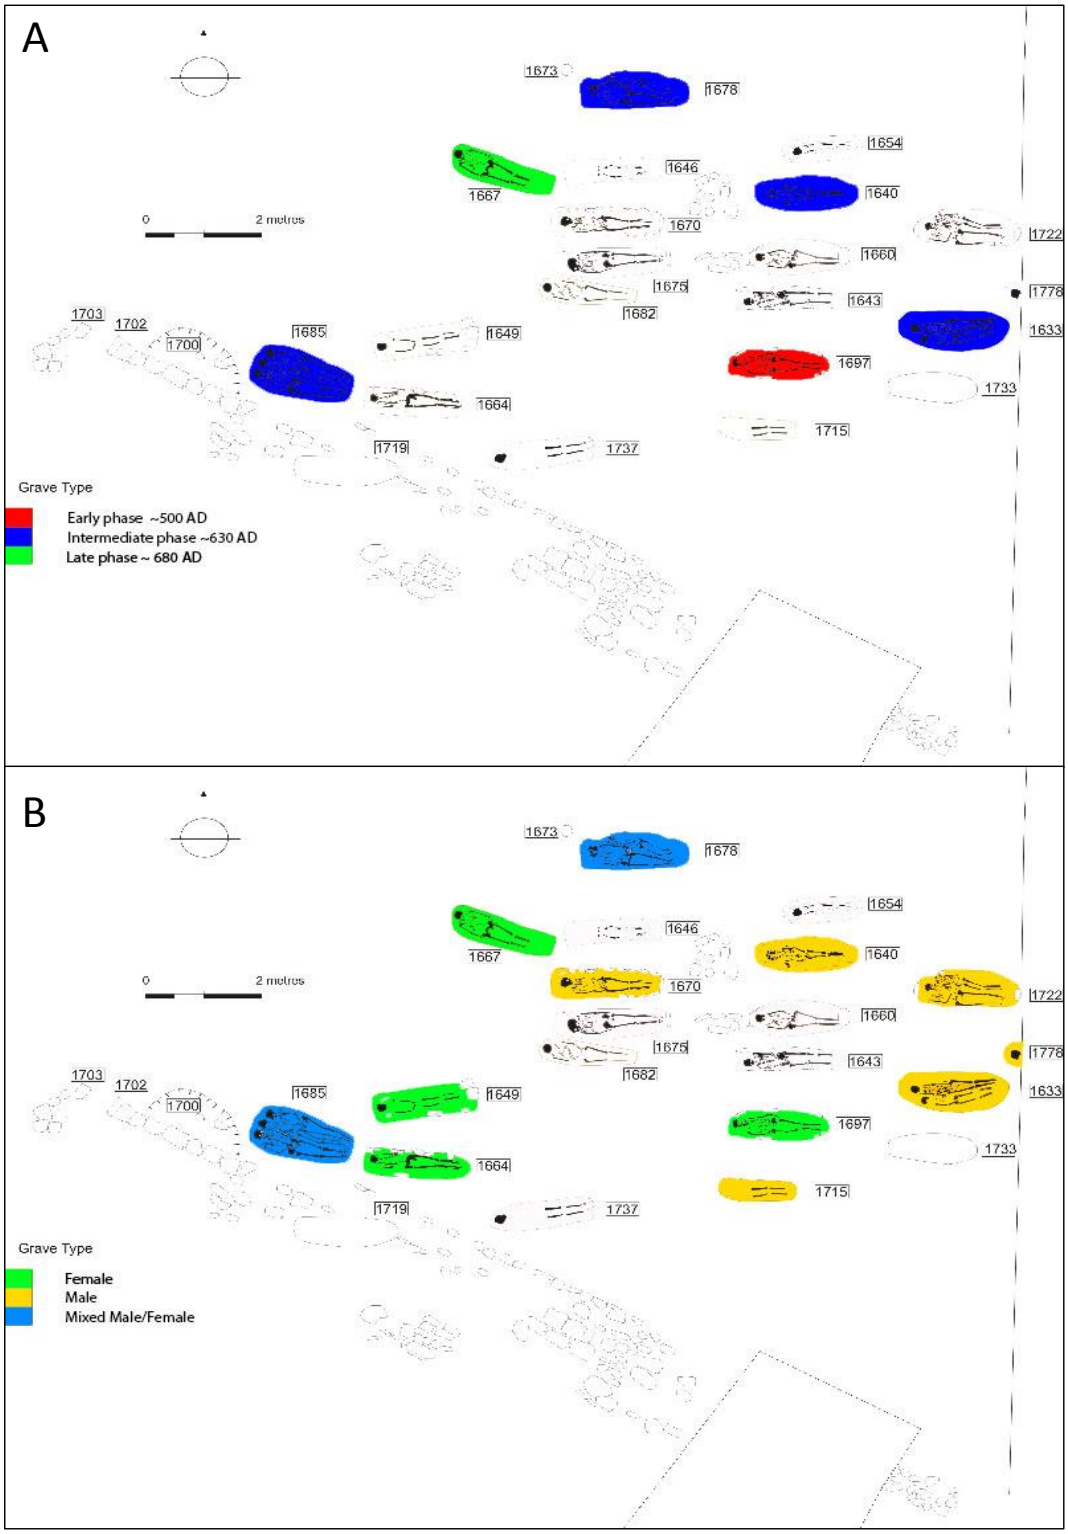

FIGURE 7.3: A - Dated individuals given as rounded mean: early phase ~500 AD; intermediate phase ~630 AD; late phase ~600 AD. B - Genetic sex: green - females (including undetermined, possible female in grave 1667); yellow - males; blue - mixed burials with at least one male and one female.

7.3.2 Dietary stable isotope analysis

One sample did not produce enough tooth powder for both DNA and stable isotope analysis and was, therefore, excluded from the stable isotope analysis. To identify the diet of the remaining 15 individuals from Worth Matravers, dietary stable isotopes were analysed and compared to seven Romano-British sites from Dorset: Alington Avenue (n = 12), Albert Road (n = 5), Gussage All Saints (n = 1), Maiden Castle Road (n = 5), Old Vicarage (n = 6), Poundbury Camp (n = 1), and Tolpuddle Ball (n = 2) (Redfern et al., 2010). The resulting plot is shown in (Figure 7.4).

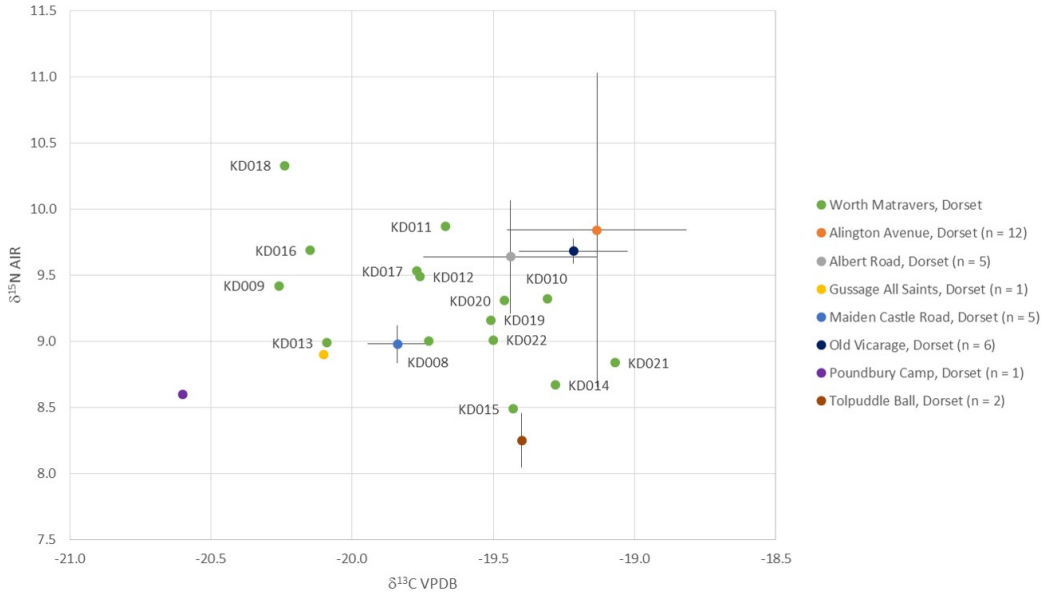

FIGURE 7.4: Dietary stable isotope analysis of the post-Roman individuals from Worth Matravers.

As can been seen, there is a huge variation seen in both carbon and nitrogen values at Worth Matravers, but this is reflected in the comparison sites. Given this variation, possible differences in nutrition in relation to burial position within the cemetery were studied (Figure 7.5). The group of individuals from the western extent of the cemetery (Figure 7.5 - West) have higher nitrogen levels than individuals in the other rows, suggesting that these people were eating a more protein-rich diet, which might indicate a higher social standing.

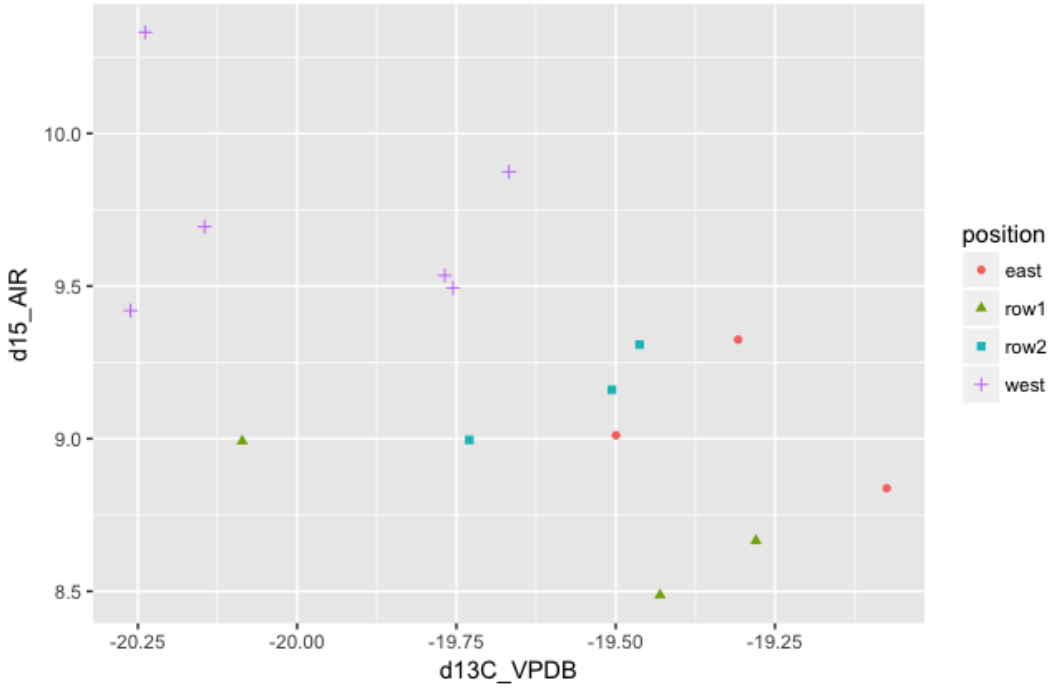

FIGURE 7.5: Dietary stable isotope data plotted by position within the cemetery.

7.3.3 Genetic sex identification

The genetic sex identification of the 16 genotyped individuals resulted in a total of ten males, five females and one individual whose sex could not be genetically identified (see Table 7.3). The layout of male and female burials is shown in Figure 7.3 B. The genetically undetermined individual is included in the females, as osteological analysis suggested that this was a female individual.

7.3.4 Mitochondrial genome analysis

Mitochondrial SNP capture was used to identify the mitochondrial haplotypes of the burials. The analysed individuals belong to nine different haplotypes (Table 7.3); four H, two U5, and one each for K1, T2 and HV. The distribution of mitochondrial haplotypes across the cemetery is shown in Figure 7.6 A.

TABLE 7.3: Uniparental haplotypes of the individuals within each grave from the post-Roman cemetery at Worth Matravers. Genetic versus osteological sex determination, and osteological age estimates of the individuals are given. Letters A, B and C indicate different individuals within one burial.

Burial number	Genetic sex	Osteological sex	Age estimate	mtDNA haplogroup	Y-chromosome haplogroup	chr Y markers
1633A	M	Undefined	adult	K1a2a	R1b1a1a2a1a2c1a2a2a1a1a	920
1640	M	Female?	17-25 years	K1a2a	I1a2a1a2∼	412
1649	F	Undefined	25-35 years	T2a1a	-	-
1633B	M	Undefined	17-25 years	U5b1	E1b1∼	382
1664	F	Female?	35-45 years	H11a	-	-
1667	U	Female?	25-35 years	HV6	-	-
1670	M	Female	17-25 years	HV6	R1b1a1a2a1a	538
1678A	M	Male	40-45 years	HV6	R1b1a1a2a1a	662
1678B	F	Undefined	15-16 years	HV6	-	-
1685A	F	Female	25-35 years	H1bb	-	-
1685B	M	Male	45-49 years	H1e1a	R1b1a1a2a1a	798

1778	M	Female	16-17 years	T2a1a	I2a1b1	279

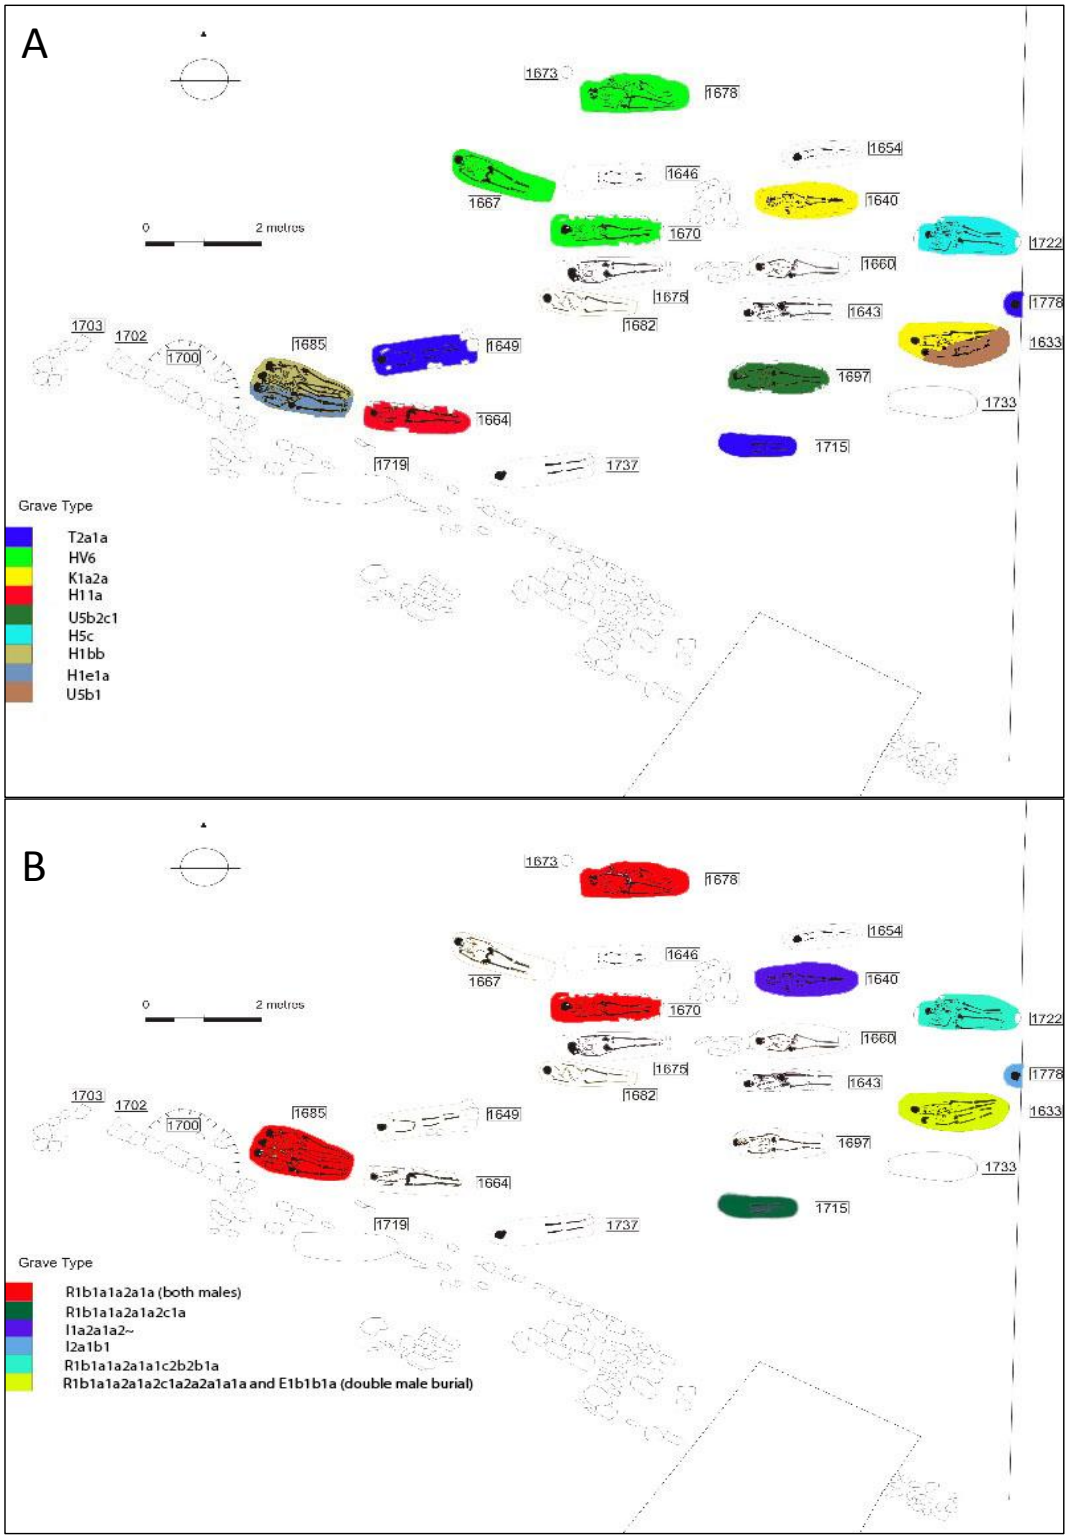

FIGURE 7.6: A - Mitochondrial haplotypes identified in the post-Roman cemetery, Worth Matravers. B - Y-chromosome haplotypes.

7.3.5 Y-chromosome analysis

Of the ten genetic males, seven were predicted to belong to different subclades of Y-chromosome haplogroup R1b, two were predicted to belong to haplogroup I, and one individual was predicted to belong to haplogroup E (Table 7.3). The distribution of Y-chromosome haplogroups within the cemetery is shown in Figure 7.6 B. Full list of all derived predictive markers can be found in Appendix G.

7.3.6 Kin relationship estimation

READ identified two first-degree (parent-offspring or siblings) and five second-degree (i.e. uncle/aunt-nephew/niece, grandparent-grandchild or half-siblings) kin relationships (Table 7.4).

TABLE 7.4: Estimated genetic kin relationships. Higher and lower class of genetic difference (Z_upper and Z_lower) are given as standard errors from the normalised mean *P*0 score.

Sample pair	Relationship	Z_upper	Z_lower
1633A+1640	second-degree	4.7258199089	-1.4743260222
1667+1670	second-degree	4.3994772251	-1.4064270971
1667+1678A	first-degree	3.126670294	-9.495248693
1678A+1670	second-degree	4.6555947222	-2.1036976561
1685A+1685C	first-degree	3.5705830828	-11.0245599904
1697+1715	second-degree	7.277960848	-0.5408975717
1715+1778	second-degree	0.1617568526	-2.6359153615

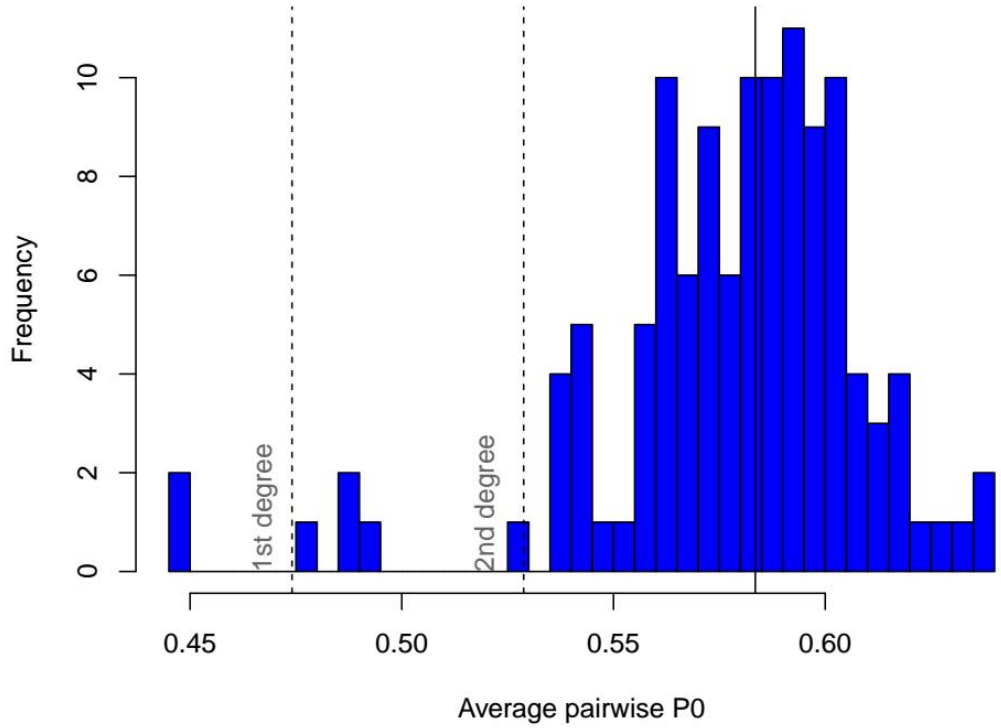

FIGURE 7.7: READ estimates for the post-Roman individuals. The histogram shows the non-normalised average *P*0 values. Vertical dashed lines show the cutoffs used to classify how the individuals were related. The solid line indicates the median value used for normalisation based on the expected value for a randomly chosen pair of unrelated individuals (Kuhn et al., 2018).

The frequency of the overall kin relationships identified using READ are shown in Figure 7.7. Burials connected through first- and second-degree kinships are shown in Figure 7.8 A and B.

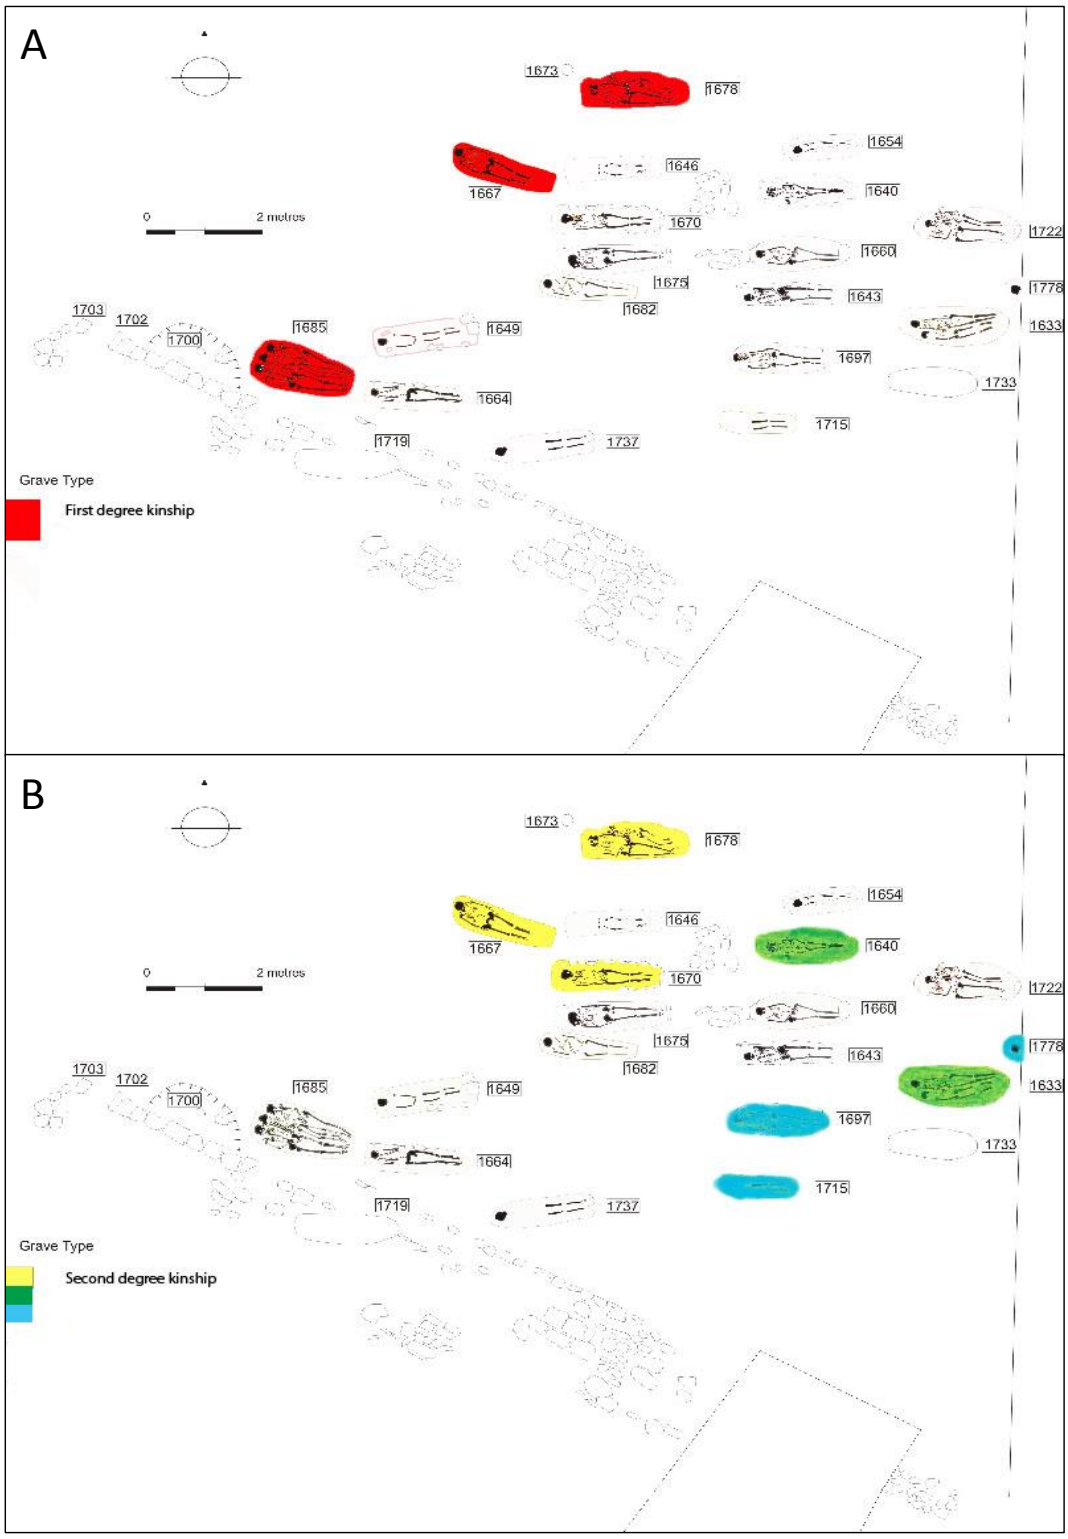

FIGURE 7.8: A - First-degree kinships. B - Second-degree kinships.

7.3.7 Principal component analysis

The post-Roman individuals fall within the modern European variation, with one sample being closer to southern Europeans and Near Eastern individuals

(Figure 7.9).

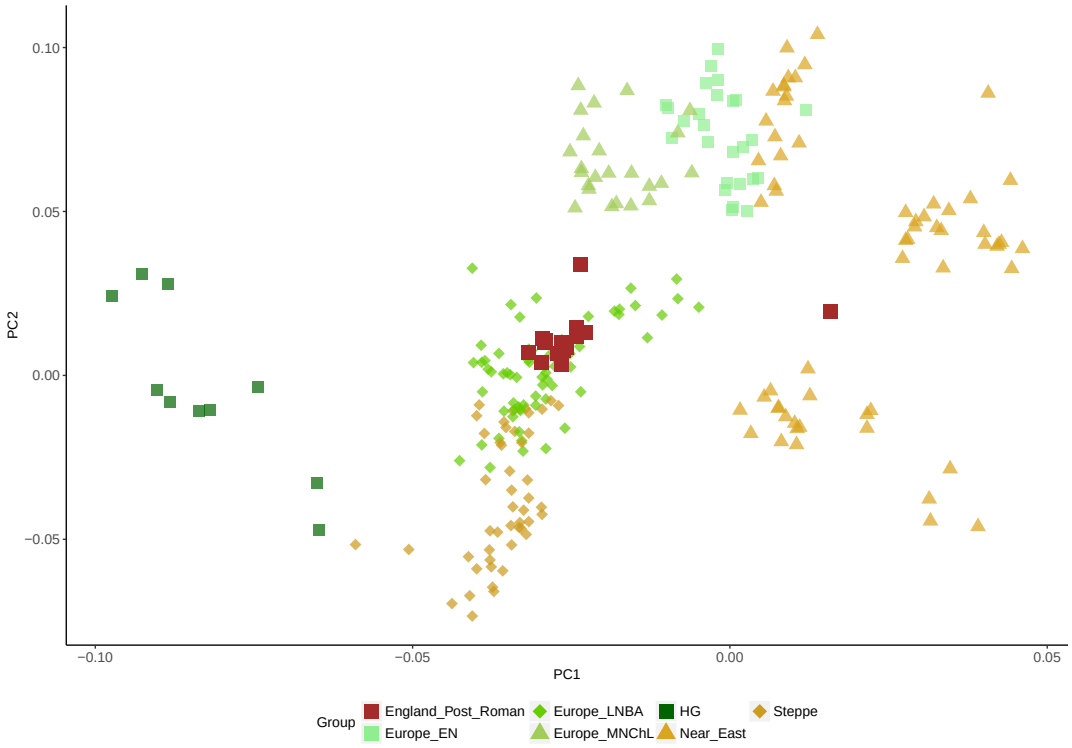

FIGURE 7.9: Principal component analysis of the 16 post-Roman individuals (green dots), with previously published modern and ancient samples of Lazaridis et al. (2016) projected onto the first two principal components.

7.3.8 ADMIXTURE analysis

The samples were merged with the publicly available datasets from Lazaridis et al. (2016) and Olalde et al. (2018). ADMIXTURE was run with cross-validation between K values 2 to 14, with K=12 giving the lowest standard error and therefore being the sensible modelling choice (Figure 7.10) (Appendix H).

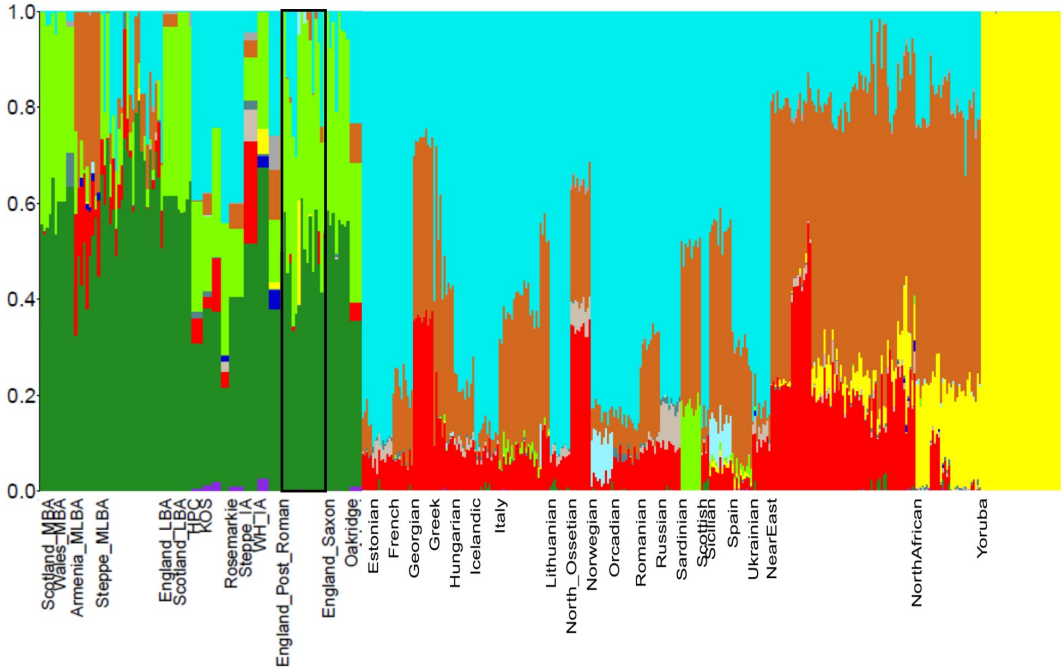

FIGURE 7.10: ADMIXTURE analysis of the post-Roman individuals with previously published modern and ancient samples of Lazaridis et al. (2016) and Olalde et al. (2018). Abbreviations used: E: Early, M: Middle, L: Late, BA: Bronze Age, IA: Iron Age, WH: West Heslerton, HPC: High Pasture Cave, KOS: Knowe of Skea.

7.4 Discussion

7.4.1 SNP capture success

The overall success rate of the 1,240K SNP capture was high, as all samples passed the quality controls, and all but one produced more than 20,000 SNPs (1678B produced <7,500 SNPs). The number of Y-chromosome markers retrieved was low, but nevertheless it was possible to predict the haplogroups as far as derived clades of the Y-chromosome tree. Similarly, the haplotyping of the mitogenomes allowed significant haplogroup assignments.

7.4.2 Radiocarbon dating

Based on radiocarbon dates (analysed by Kruz 2018), the cemetery was in use for less than 200 years and several of the dated burials have overlapping dates (Figure 7.11).

Burials belonging to the intermediate phase, with almost identical dates, contain the triple burial of a family (1685), the two double burials (1678 and 1633), and one single burial (1640). The case of, the multiple burial of three

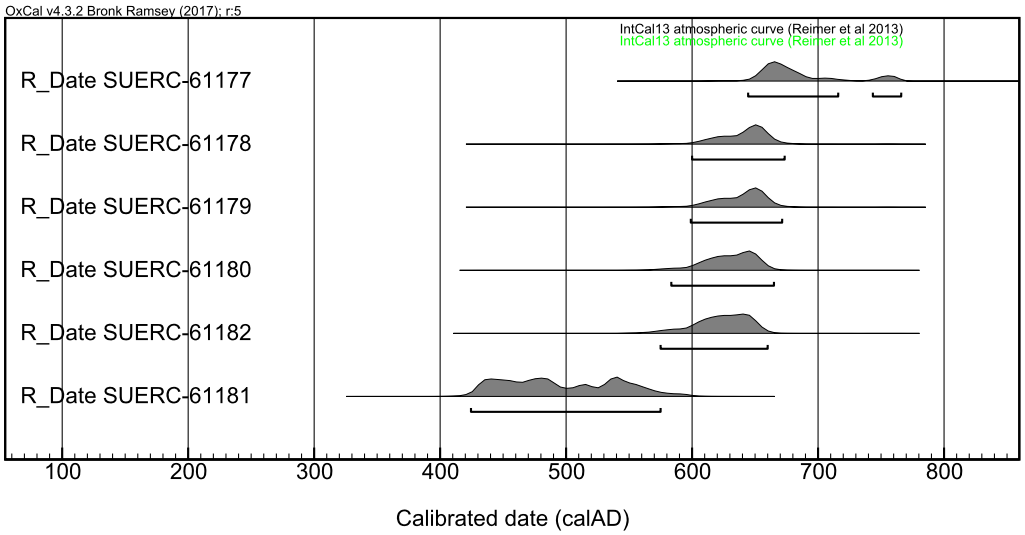

FIGURE 7.11: Calibrated radiocarbon dates of the dated individuals from Worth Matravers. The corresponding grave numbers to the SUERC codes are as follows: SUERC-61177 - grave 1667, SUERC-61178 - grave 1633, SUERC-61179 - grave 1640, SUERC-61180 - grave 1678, SUERC-61181 - grave 1697, SUERC-61182 - grave 1685.

individuals of different ages suggests that these people likely passed away contemporaneously, possibly due to disease.

7.4.3 Anglo-Saxon diet

The dietary stable isotopic analysis identified two main groups within the cemetery. Individuals buried on the western side of the cemetery have a higher nitrogen intake and so had a more terrestrial/meat-based diet. All the other individuals have a comparably lower nitrogen level, suggesting a slightly more marine influence; most likely from shellfish. Compared to published dietary stable isotope data from Anglo-Saxon sites in Dorset, the post-Roman individuals from Worth Matravers had a comparably more marine-based diet of low trophic animals and plants, showing lower trophic levels than individuals from Alington Avenue, Old Vicarage, and Albert Road (all Anglo-Saxon sites in Dorset). Their diet was possibly based on shell fish and sea weed, as they were close to the coast. They were most similar to Anglo-Saxon individuals from Maiden Castle Road (Dorset), Albert Road (Dorset), and Alington Avenue (Dorset). However, the range of $\delta^{13}C$ and $\delta^{15}N$ values of these individuals is quite large and implies different ways of subsistence among these populations, with rather strong differences in protein intake based on plants and/or animals.

7.4.4 Estimated kin relationship

The only triple burial is also the only excavated cist-burial (grave 1685), which includes one female aged 25-35 years, a male aged 45-49 years and a male adolescent. Based on the analysis of their uniparental markers and kinship analysis, it is very likely that this burial contains a family. Both the adult female and the adolescent man share the same mitochondrial haplotype (H1bb), suggesting a mother-son relationship, and the male and the adolescent share the same Y-chromosome haplotype (R1b1a1a2a1a), suggesting a father-son relationship. READ identified a first-degree (parent-offspring or siblings) kin relationship between the adult female and the adolescent, whereas no kin relationship between the adult male and young man could be identified. However, this might be a false negative assignment due to low coverage of the data.
The kin relation of the individuals in burials 1667 and 1670, and double burial 1678 is particularly interesting. All four individuals share the same mitochondrial haplogroup, HV6. The two men in burials 1670 and 1678 share the same Y-chromosome haplogroup (R1b1a1a2a1a), which is the same as the two men in the triple burial (1685). Based on the kinship analysis, the young woman in the double burial 1678 does not have first- or second-degree kinship to any of the other three individuals and will thus be excluded from further discussion of the degrees of relationship between the individuals in these three graves. The possible female individual in grave 1667 and the old man in grave 1678 are first-degree related, whereas the man in burial 1670 shares second-degree kinship with them both (Figure 7.12 - A). The potential scenarios of kinship among them are not very straightforward. Assuming the burial of the female is about 50 years younger (based on the age difference; the female is 25-35 and the male is 40-45) than burial 1678 of the older man, a mother-son relationship can be excluded. This leaves either a:

1. father-daughter kin relationship; or

2. sibling relationship

The sibling scenario is quite unlikely given the age difference of the individuals and the radiocarbon age difference of the graves. However, the standard errors of the radiocarbon dates are slightly overlapping, which means the burials could be contemporaneous. It is possible that, due to low coverage data, the kin relationship has been classified as first-degree, while in reality it is a second-degree kinship and the individuals have an uncle-niece

or grandparent-granddaughter relationship. As the samples had more than 1,000 overlapping SNPs the likelihood for a false positive degree classification is <2% (Kuhn et al., 2018). Otherwise this would suggest that the two individuals have a father-daughter relationship and the shared mitochondrial haplogroup is due to inbreeding in the maternal lineage.
The second-degree kinship of the man in burial 1670 with both these people suggests either that:

1. the man in burial 1670 is the uncle or grandfather of both the woman in burial 1667 and the man in 1678. This would mean that these two are siblings rather than father and daughter; or

2. the man in burial 1670 is the half-sibling of the man in burial 1678 and the uncle of the woman, so the first-degree kinship between 1667 and 1678 explains an offspring-parent relation.

Although, it is not possible to identify one specific kinship scenario, the shared mitochondrial haplogroup and shared Y-chromosome haplogroup between these individuals suggest close familial kin relationships. This is supported by the kinship analysis, even if inaccurate assignments of first- or second-degree kinship have to be accounted for, due to low coverage data.
Unfortunately, there are no stable isotopic or genetic data available for the three individuals that are buried in graves 1646, 1675 and 1682, which are neighbouring graves of the three genotyped ones (Figure 7.8). Based on the close proximity of these graves, and the familial relationships between the individuals analysed, it is possible that the people with missing data may share familial bonds with those analysed. Further sampling and genetic analysis would elucidate if the proximity of the graves of these individuals is based on familial bonds or by chance.
The three individuals in burials 1649, 1715 and 1778 share the same mitochondrial haplogroup, whereas the Y-chromosomes of the men in burials 1715 and 1778 are different, R1b1a1a2a1a2c1a and I2a1b1, respectively. Therefore, any familial kinship is more likely to be maternal. Kinship analysis could not pick up any first- or second-degree relation between the woman and either of the two men, but a second-degree kinship could be identified between the males. This means they are either grandfather and grandson or uncle and nephew (see Figure 7.12 - B). Furthermore, a second-degree kinship was identified between the man in grave 1715 and the woman in grave 1697. As they have very different mitochondrial haplotypes, T2a1a and

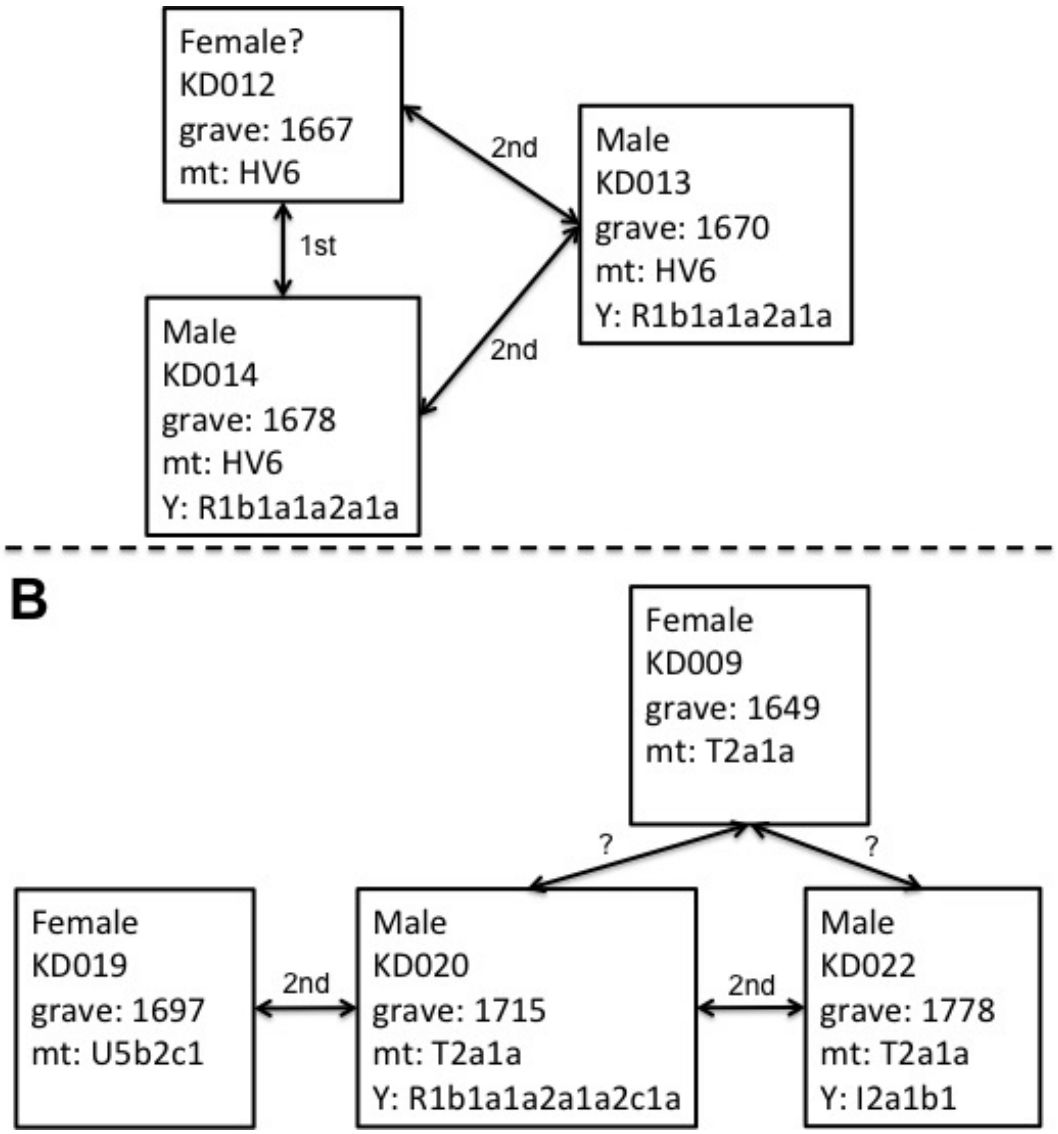

FIGURE 7.12: Schematic of estimated kin relationships within the post-Roman cemetery, Worth Matravers. A - Kin relationships between burials 1667, 1670 and 1678. B - Kin relationships between burials 1649, 1697, 1715 and 1778.

U5b2c1, respectively, they are very likely paternally related; either grandfather and granddaughter or uncle and niece; although another possibility would be that they shared the same father but had different mothers.
Other second-degree kinships were identified between the man in burial 1640 and the older man in the double burial 1633. Possible kin relationships between them are:

1. half-siblings – same mother, different fathers; or

2. uncle and nephew.

Interestingly, the older male in the earth-cut double burial (grave 1633), who had his head resting on a stone anchor, was buried with a young male who

has a mitochondrial haplotype belonging to U5b1 and a Y-chromosome haplotype belonging to E1b1∼, with the most predictive markers being L507, L535 (more downstream predictive markers CTS10775 and CTS3171, were inconclusive as they point to different branches). Although, it was not possible to predict a more downstream haplogroup of E1b1∼ due to low coverage of the Y-chromosome SNPs, no contradictory markers were identified, making the prediction of E1b1∼ most likely. Both uniparental markers of this young man have not been identified in any other person within the cemetery. As there seems to be no apparent kin relationship between him and the older man he was buried with, the type of burial with the anchor suggests a work relationship, such as an apprentice. Possibly they were both fishermen. Such a mixed burial of an immigrant and a local has not yet been documented.
The two individuals in single burials with no apparent kinship relations to anyone analysed samples are: a female in grave 1664 with mtDNA haplotype H11a and a male in grave 1722 with mtDNA haplotype H5c and Y-chromosome haplotype R1b1a1a2a1a1c2b2b1a.

7.4.5 Social structure found within the cemetery

The west-east gradient imposed by the stable isotope data on the schematic of the cemetery suggest that familial bonds were not the important factor for the proximity of familial burials in all cases. An example is burial 1649, which shared the maternal lineage with individuals buried further east in the cemetery. This might be due to interment at a different time, but could also be due to a different social status, which led to better access to food or they were very distant relatives, as the kinship analysis did not suggest any close kin relationship.
The analysis of uniparental markers suggests patrilocality at the site, and the overall layout of the cemetery seems to be based on familial bonds and kin relationships, as multiple burials contain either entire families or graves of family members are closely placed. Overall, no female to female first- or second-degree kinship could be observed, whereas male to male first-degree and second-degree kin relationships were prevelant. This supports patrilocality within the site.

7.4.6 Genome-wide analysis

Autosomal analysis of the 16 post-Roman individuals showed that they all clustered with ancient European Late Neolithic/Bronze Age people, with

the exception of one individual (KD010, 1633B) who clustered closest with ancient Near Eastern samples (Figure 7.9). ADMIXTURE analysis showed that this individual shared ∼50% of its ancestry with modern Near Eastern/North Africans. As he belongs to a typical European mitochondrial haplogroup, but has a Near Eastern/North African Y-chromosome haplogroup, and based on the proportions of European and North African ancestry components, it is most likely that he had a mother from northwest Europe and a Near Eastern/North African father. An individual with Near Eastern ancestry has been reported from a Roman cemetery in York, England (Martiniano et al., 2016). These people are evidence of long-distance migrations and diversity during the Roman Empire, which appears to have lasted into the post-Roman era.

Chapter 8

Multi-period West Heslerton, East Yorkshire

8.1 Introduction

The Early Anglo-Saxon or Anglian cemetery at West Heslerton, North Yorkshire, was discovered during mineral excavation operations at Cook's Sand Quarry (Haughton et al., 1999b) (Figure 8.1). The discovery of the site led to an archaeological rescue excavation that was conducted between 1977 and 1987 (Haughton et al., 1999b).

The first documented occupation at the site was found to date back to the Late Mesolithic, when the area was used for flint knapping, and there is evidence that people continued to live there up into the Bronze Age. During the Late Neolithic and Early Bronze Age, the site was used for rituals and the establishment of a field system was attempted, as well as the foundation of two Early Bronze Age (EBA) barrow cemeteries (Haughton et al., 1999b). One of the EBA cemeteries produced an important series of Food and Beaker vessels (Powlesland et al., 1986). Woodland regenerated in the area after the cemeteries went out of use during the late Bronze and early Iron Ages, but then the site was once again continuously occupied throughout the Roman and Anglo-Saxon periods, with evidence of settlement from the Late Iron Age onwards (Haughton et al., 1999b). The Anglo-Saxon, or Anglian, cemetery is the only case in the North of England where this combination of cemetery and settlement have been investigated together (Haughton et al., 1999b).

The rescue excavation examined 11 prehistoric burials and 201 out of an estimated 300 Anglian burials, consisting of both inhumations and cremations. The Anglian cemetery was established in the late 5th century within an area defined by an earlier Late Neolithic and Early Bronze Age ritual complex. The cemetery was in use for not more than 200 years until the 7th century

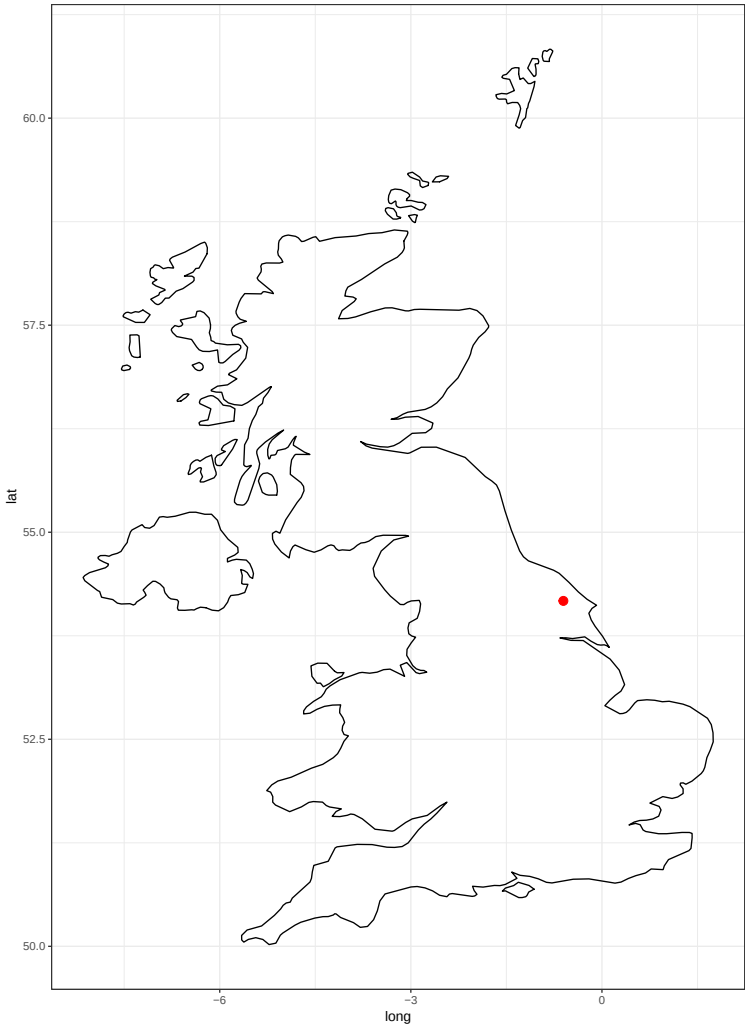

FIGURE 8.1: The location of West Heslerton within the British Isles.

AD, which does not cover the entire occupation period of the associated settlement (Haughton et al., 1999a; Haughton et al., 1999b).

The bone preservation of the Anglo-Saxon inhumations was very poor. Half of the graves contained either no skeletal material or only fragments of bone or tooth enamel, which is due to the well-drained sandy soil (Haughton et al., 1999b). Preservation was better only in a few graves in an excavation area with chalk soil. In contrast, the few Bronze Age and Iron Age burials had a much better preservation of skeletal material, which according to Haughton et al. (1999b) is possibly due to being buried in soil substrates with more chalk inclusions.

Nearby the Anglo-Saxon cemetery, two female Iron Age individuals were excavated from Arras burials at Knapton Wold, West Heslerton. The female skeletons were well preserved and assumed to be related to each other.

As their burials were associated with the settlement in West Heslerton, they were analysed together with the individuals from the Bronze Age and Anglo-Saxon cemetery. A total of 97 samples, mainly petrous bones, other cranial fragments and teeth, were selected. Of these, a total of the 15 best preserved individuals from the Bronze Age and Anglo-Saxon period were sampled for genetic analysis. The cemetery in West Heslerton offers the opportunity to analyse genomic data from individuals from different time periods in a continuously occupied area.

8.2 Materials and Methods

Skeletal remains were assessed for preservation and the best preserved samples from different time periods were sampled for genetic analysis. In total, four Bronze Age individuals, two Iron Age individuals and nine Anglo-Saxon individuals were analysed by sampling petrous bones.

TABLE 8.1: Processed samples from West Heslerton. Analysis types: L – NBAF Liverpool; M – Macrogen; R – Reich, Harvard Medical School.

DNA code	DNA sample	Analysis type	Era	Sample code
KD002	petrous	L	Anglo-Saxon	HP2BA100
KD003	petrous	L	early Bronze Age	HP2BA283 AN 1806
KD031	petrous	R	Anglo-Saxon	HP2BA790 AH 10139

8.2.1 Ancient sample processing

Ancient DNA sample processing was undertaken at the Ancient DNA Facility of the University of Huddersfield, and the Ancient DNA Lab, Smurfit Institute, Trinity College Dublin (TCD) (Ireland), under dedicated clean-room conditions. The same protocol for sample processing and ancient DNA extraction was used in both labs.

8.2.2 Sampling and DNA extraction

Sampling and DNA extraction was undertaken at both laboratories as outlined in Chapter 6. Dietary stable isotope sampling of KD071 and KD072 followed as outlined in Chapter 2.

8.2.3 Library preparation and sequencing

8.2.3.1 Library preparation

Libraries for shot-gun sequencing of seven samples (four Bronze Age, two Iron Age and one Anglo-Saxon individual) were prepared. Library preparation followed the protocol described in Chapter 2. One single-indexed library was prepared at TCD for samples KD002 and KD003. Eleven further libraries were prepared at the University of Huddersfield. For KD002 and KD003, three libraries each were dual-indexed and one single-indexed library each was prepared for samples KD039, KD040, KD041, KD071 and KD072. The same protocol was used in both labs, with the only difference being the single- and dual-indexing. For further details see Chapter 6.

8.2.3.2 Sequencing

The NGS libraries prepared at TCD were sequenced in an Illumina HiSeq 2000 (single-index, 100 base pair, single-end sequencing; Macrogen, South Korea), with library codes KaD2 and KaD3 (equivalent to samples KD002 and KD003, respectively). NGS libraries prepared at the University of Huddersfield were sequenced in an Illumina HiSeq 2000 (dual-index, 100 base pair, single-end sequencing; NBAF Liverpool, United Kingdom) [with library codes KD002.1, KD002.2, KD002.3, KD003.1, KD003.2 and KD003.3], and in an Illumina HiSeq4000 (single-index, 100 base pair, paired-end sequencing; Macrogen, South Korea) [with library codes K1, K2, K3, K22 and K24, for samples KD039, KD040, KD041, KD071 and KD072], respectively. Dual-indexing was undertaken due to the requirements of NBAF Liverpool, and single-end versus paired-end sequencing at Macrogen was based on the offer given per lane.

8.2.4 Data processing and read mapping

The NGS reads of all single-end sequenced libraries were trimmed using cutadapt version 1.13 (Martin, 2011), whereas the NGS reads of paired-end sequenced libraries were trimmed using AdapterRemoval version 2.1.7 (Schubert et al., 2016). For further details please refer to Chapter 6. Read files for the multiple libraries of KD002 and KD003 were merged using samtools merge. The detailed steps of analysis are described in Chapter 2. Kinship analysis was carried out using READ (Relationship Estimation from Ancient DNA)(Kuhn et al., 2018). As the obtained data had very low coverage, and the vast majority of positions were only covered by a single read, all genotypes were converted to homozygous. Genetic sex determination was undertaken using the script by Skoglund et al. (2013). Y-chromosome haplogroup determination was carried out using Yleaf (Ralf et al., 2018). In order to compare the newly generated ancient dataset to modern human populations, bases to known SNP positions of the publicly available Lazaridis et al. (2016) dataset were used and SNPs were filtered as described previously (Lazaridis et al., 2016). Principal Component Analysis was run using smartpca of the EIGENSOFT package (Patterson et al., 2006; Price et al., 2006) and plotted with R version 3.4.4 (R Core Team, 2018). A combined dataset of the newly generated genotypes, together with the reference panel, was run using ADMIXTURE (Alexander et al., 2009).

8.2.5 SNP capture

DNA extracts of eight Anglo-Saxon samples were shipped to collaborator David Reich (Harvard Medical School) for enriched 1.2M SNP and mitogenome capture. Data processing followed the pipeline used in Olalde et al. (2018).

8.3 Results

Overall sequencing results are given in Table 8.2. Information on the negative controls can be found in Appendix D.

TABLE 8.2: Sequencing results of all shotgun-sequenced samples from West Heslerton and Knapton Wold. 'SNPs' denotes the number of SNPs called with the published datasets as reference panel.

Age	Lab ID	Read count	Endogenous content in %	Duplication rate in %	Genome coverage	Chr. Y haplogroup markers	SNPs
Bronze Age	KD003	3,893,102-23,948,074	9.36-28.4	1.1	0.1608	–	90,090
	KD039	75,915,892	9.74	0.1319	0.0078	4,914	4,311
	KD040	70,076,838	9.97	0.1105	0.0152	324	9,084
	KD041	81,678,236	13.38	0.1137	0.0267	672	16,544
Iron Age	KD071	116,208,258	7.86	0.1009	0.0186	–	12,134
	KD072	76,431,932	11.83	0.1111	0.0159	–	10,303
Anglo-Saxon	KD002	21,712,945-93,412,198	0.34-1.89	0.32	0.0265	–	16,294

Detailed endogenous contents of the two samples KD002 and KD003, consisting of multiple libraries, are given in Table 8.3.

TABLE 8.3: Read count and endogenous contents of KD002 and KD003 libraries. Indexing type indicates whether a library was single or dual indexed. Read type indicates single-end (SE) and paired-end (PE) sequencing.

Lab ID	Read count	Endogenous content in %	Indexing type	Read type
		KD002		
KaD2	93,412,198	0.34	single	SE
KD002.1	29,201,886	1.65	dual	PE
KD002.2	22,710,532	1.69	dual	PE
KD002.3	21,712,945	1.89	dual	PE
		KD003		
KaD3	23,948,074	9.36	single	SE
KD003.1	14,539,263	28.06	dual	PE
KD003.2	17,144,472	28.23	dual	PE
KD003.3	3,893,102	28.40	dual	PE

Because the endogenous content of the Anglo-Saxon sample KD002 was very low in all libraries, it was decided to try the SNP capture approach on the remaining Anglo-Saxon samples, rather than shot-gun sequence them. The SNP capture results of the eight additional Anglo-Saxon samples are given in Table 8.4.

TABLE 8.4: SNP capture results of the Anglo-Saxon samples.

Sample ID	Coverage	SNPs hit on autosomes	chr. Y haplogroup markers
KD031	0.6210	439,024	4,914
KD032	0.3823	340,551	3,641
KD033	0.6914	509,157	–
KD034	0.6412	476,232	5,404
KD035	0.9794	601,957	–
KD036	0.2141	221,669	2,448
KD037	1.8333	691,863	–
KD038	1.0694	605,796	7,610

8.3.1 Genetic sex identification

The genetic sex of the shot-gun sequenced individuals, as determined by the Skoglund script (Skoglund et al., 2013), the Skoglund score (Skoglund et al., 2015) and karyotype plotting, is given in Table 8.5. As the sex of three of the shot-gun sequenced samples could not be determined by using the script (Skoglund et al., 2013), karyotype plotting and X-chromosome percentage calculation were used as aids to identify the genetic sex of the individuals (for details see Appendix E). Overall, four individuals were female and three were male.

TABLE 8.5: Genetic sex determination of shot-gun sequenced samples from West Heslerton using the Skoglund script [1] and the Skoglund score [2]. Samples in date order.

Age	Sample ID	Sex deter. based on [1]	Chr. X in %	Sex deter. based on [2]
Bronze Age	KD003	XX	–	–
	KD039	Not assigned	55.2	XY
	KD040	consistent with XY but not XX	50.8	XY
	KD041	XY	–	–
Iron Age	KD071	Not assigned	78.2	XX
	KD072	Not assigned	75.0	XX
Anglo-Saxon	KD002	XX	–	–
	KD031	XY	–	–
	KD032	XY	–	–
	KD033	XX	–	–
	KD034	XY	–	–
	KD035	XX	–	–
	KD036	XY	–	–
	KD037	XX	–	–
	KD038	XY	–	–

8.3.2 Dietary stable isotope analysis

In order to identify the diet of the two Iron Age samples from Knapton Wold (KD071 and KD072), dietary stable isotopes were analysed and compared to four other Iron Age sites from East Yorkshire: Garton Slack (n = 2); Kirkburn (n = 1); Wetwang Slack (n = 27); and Wetwang Village (n = 1); (Jay et al., 2013). The two individuals were eating very different diets, as can been seen in Figure 8.2.

8.3.3 Mitochondrial genome analysis

The coverage of the shot-gun sequenced mitochondrial genomes ranged from 0.9055x to 26.358x. The coverage of KD039 was too low to determine the mtDNA haplogroup. For Anglo-Saxon samples KD031 to KD038 no genome coverage and standard deviation are available, as these samples were typed using a capture array. Detailed mutation lists per individual can be found in Appendix F.

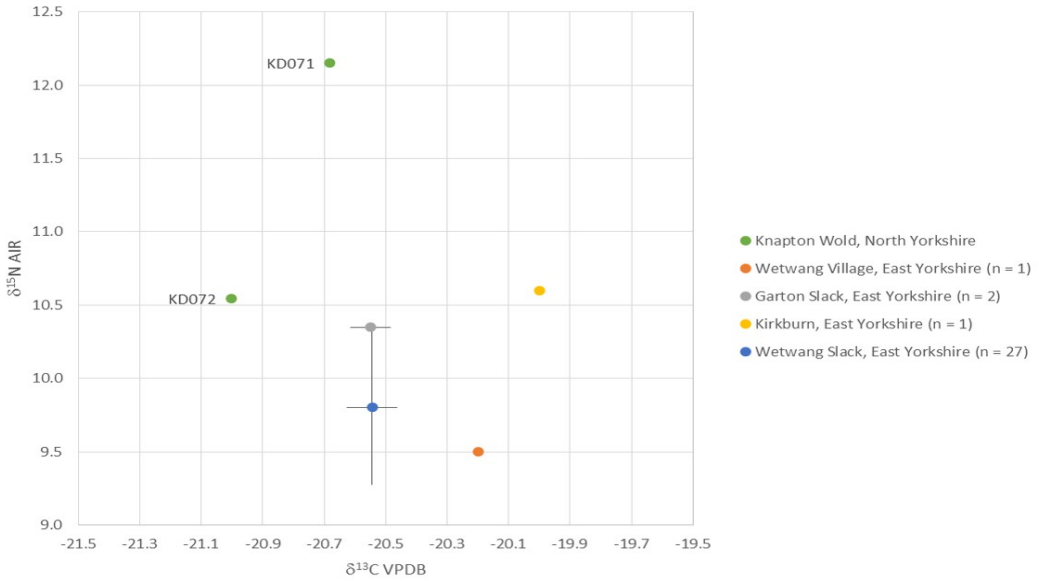

FIGURE 8.2: Dietary stable isotope analysis of the two Iron Age individuals from Knapton Wold (West Heslerton), compared to four other Iron Age human assemblages from East Yorkshire (Jay et al., 2013).

TABLE 8.6: Mitochondrial haplogroup assignment of the shot-gun sequenced samples from West Heslerton and Knapton Wold.

Sample ID	mitogenome coverage	std deviation	mtDNA haplogroup
KD003	26.358	5.2719	T2e
KD039	0.9055	1.7292	–
KD040	2.3820	1.9072	T2b4h

KD002	3.2841	1.8178	H6a1a
KD031	–	–	H1c1
KD032	–	–	H1q
KD033	–	–	H1b
KD034	–	–	X2b4a
KD035	–	–	U5a1a1e
KD036	–	–	K1d1
KD037	–	–	T2b2b
KD038	–	–	K1a4a1a+195

8.3.4 Y-chromosome analysis

One of the three shot-gun sequenced males from the Bronze Age did not have enough coverage to predict the Y-chromosome haplogroup (KD039). However, for the remaining samples, KD040 and KD041, and the five Anglo-Saxon males, the predicted Y-chromosome haplogroups are given in Table 8.7. Detailed lists of retrieved derived predictive markers per individual can be found in Appendix G.

TABLE 8.7: Predicted Y-chromosome haplogroups of the West Heslerton Anglo-Saxon individuals.

Sample ID	Predicted Y-chromosome haplogroup	Most downstream predictive markers
KD031	R1b1a1a2a1a1	F69 PF6438 L23 L51 L151 M405
KD032	R1b1a1a2a1a1	CTS894 PF6430 PF6438 M405

8.3.5 Principal component analysis

Principal component analysis (PCA) shows the Bronze Age, Iron Age and Anglo-Saxon individuals plotting closest with the European Late Neolithic and Bronze Age individuals (Figure 8.3).

8.3.6 ADMIXTURE analysis

The lowest cross-validation error obtained for the ADMIXTURE run of the shot-gun sequenced individuals was K=12 (Figure 8.4). Using the shot-gun sequences, only two individuals (both Bronze Age; KD003 and KD041) had enough SNPs overlapping with the published dataset on which ADMIXTURE could be run. The remaining Bronze Age, the two Iron Age samples and the single Anglo-Saxon sample did not produce enough SNPs and were, therefore, excluded from the analysis.

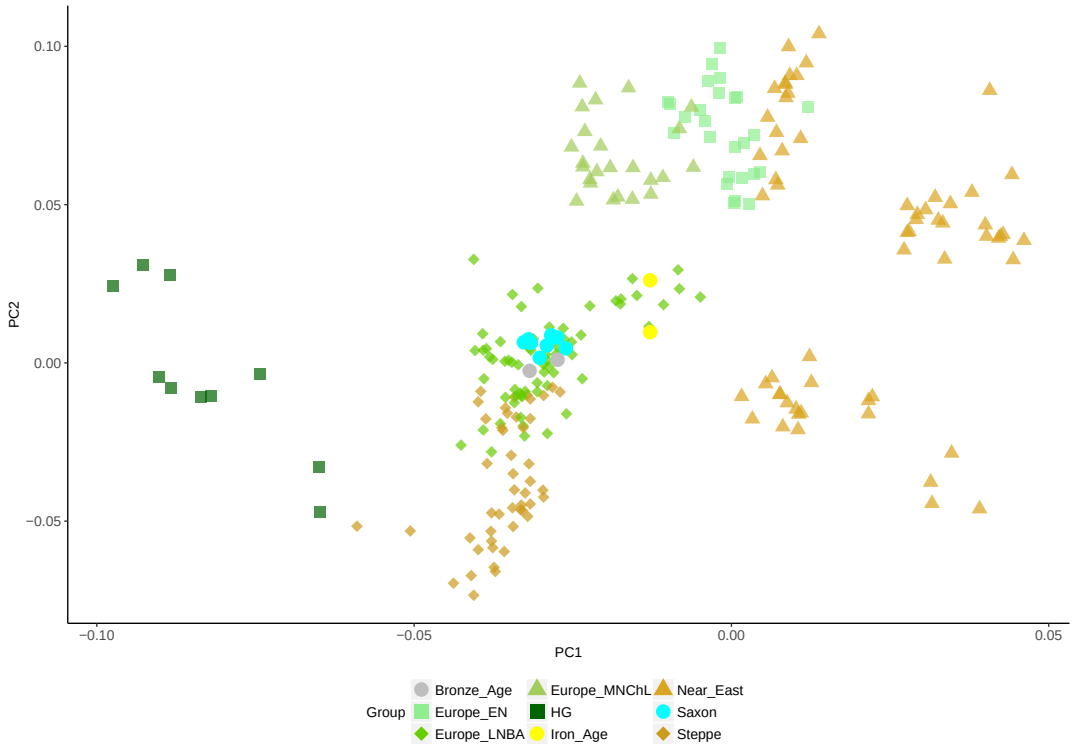

FIGURE 8.3: Principal component analysis of the individuals from West Heslerton, together with previously published ancient samples of Lazaridis et al. (2016).

8.4 Discussion

8.4.1 Sequencing success

All samples from all time periods of West Heslerton and Knapton Wold were successfully sequenced. Of the four Bronze Age individuals, three were determined as male and one as female. Although one sample (KD039) did not produce enough coverage of the mitochondrial genome to determine its haplogroup, the other three (KD003, KD040 and KD041) belonged to mitochondrial haplogroups T2e, T2b4h and U5a1a2a, respectively. The determined Y-chromosome haplogroups for samples KD040 and KD041 were predicted as R1b1a1a2a and R1b1a1a2.

8.4.2 The Bronze Age individuals from West Heslerton

The mitochondrial haplogroup T2e dates to ∼11 kya and appears to be predominantly Mediterranean and southern European (Pala et al., 2012). Its distribution ranges as far as Iceland and Scandinavia in northern Europe, as well as, with low frequency, the Near East. It has already been found in Mesolithic (Bramanti et al., 2009) and Neolithic Germany (Haak et al.,

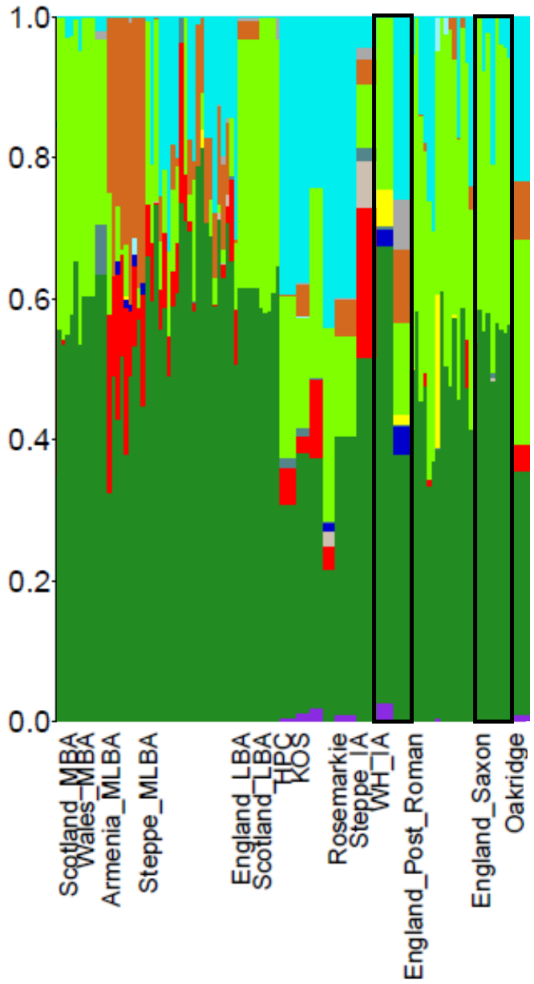

FIGURE 8.4: ADMIXTURE analysis of the individuals from West Heslerton, with previously published ancient samples of Lazaridis et al. (2016) and Olalde et al. (2018) for K=12. Abbreviations used: E: Early, M: Middle, L: Late, BA: Bronze Age, IA: Iron Age, WH: West Heslerton, HPC: High Pasture Cave, KOS: Knowe of Skea.

2015), Neolithic Scotland (Tulloch of Assery B, Highland), Middle Bronze Age England (Amesbury Down, Wiltshire) and in a Bell Beaker burial from Poland (Olalde et al., 2018). The Polish Bell Beaker individual also carried Y-chromosome haplogroup R1b1a1a2, similar to the two Bronze Age males from West Heslerton. Haplogroup T2b is considered to encompass about half of T2 amongst Europeans (Pala et al., 2012). It dates to ∼10 kya and is predominantly European. Although most of the larger subclades of T2b are predominantly found in Europe, gene flow into the Near East has been detected, with T2b4 being a clear example which includes small derived clades that have spread as far as Nepal (Pala et al., 2012). T2b is suggested to have

dispersed into Europe during the early Neolithic period and it has been identified in multiple Neolithic remains from Southern, Central and Northern Europe (Haak et al., 2005; Bramanti et al., 2009; Malmström et al., 2009; Haak et al., 2010; Lacan et al., 2011a; Lacan et al., 2011b; Allentoft et al., 2015; Haak et al., 2015; Mathieson et al., 2015; Lazaridis et al., 2017; Lipson et al., 2017; Nikitin et al., 2017; Fernandes et al., 2018; Mathieson et al., 2018; Mittnik et al., 2018; Olalde et al., 2018). To date, two ancient mitochondrial genomes belonging to T2b4 have been reported. One Late Bronze Age male from Srubnaya, Russia, with Y-chromosome haplogroup R1a1a1b2 (Mathieson et al., 2018), and one Middle Bronze Age male from Baston, Lincolnshire, who belonged to Y-chromosome haplogroup R1b1a1a2a1a2 (Olalde et al., 2018).
U5 is the most ancient European mitochondrial haplogroup and arose in the Upper Palaeolothic among the first settlers (Malyarchuk et al., 2010b). Subclade U5a dates to ∼16-20 kya. The origin of this cluster has been indicated to be eastern Europe, due to the presence of old U5a1 lineages there (Malyarchuk et al., 2010b). Four ancient individuals belonging to U5a1a2a have previously been reported. One Late Neolithic German individual (Haak et al., 2015), two Bronze Age individuals from England and Russia (Allentoft et al., 2015; Olalde et al., 2018), and one individual from the Hungarian conquest period (Neparáczki et al., 2017). The reported Bronze Age individual from Hasting Hill, Sunderland, was determined as male and its Y-chromosome haplogroup was R1b1a1a2a1a2.

8.4.3 The Iron Age individuals from Knapton Wold

The two analysed Iron Age individuals were thought to be related based on their burial arrangement. They were both determined as genetically female, which supports the osteological analysis, and both shared the same mitochondrial haplogroup, H1b1+16362. However, unfortunately their genome coverage was too low to use READ analysis to detect kin relationship. To date the only ancient individual reported to belong to the same mitochondrial haplogroup has been from Bell Beaker Germany (Olalde et al., 2018). The dietary stable isotope analysis of these two individuals showed that, as well as their diets differing from other Iron Age sites in Yorkshire, they themselves were eating surprisingly different diets from each other. Although the carbon values are very variable across the sites included in the comparison, apart from KD071 the nitrogen values are similar, which is indicative that all individuals had a similar amount of protein intake in their diet. The high nitrogen value seen in KD071 may be due to an increased marine input into

her diet. The variation in carbon is most likely explained by the amount of fish in the diet at each site, with KD072 having the least amount. The difference seen between KD071 and KD072 is very striking, but requires analysis of more individuals, as well as comparative faunal data, to be studied in more detail.

8.4.4 The Anglo-Saxon individuals from West Heslerton

Of the analysed Anglo-Saxon individuals (one shot-gun sequenced individual and eight SNP capture sequenced individuals), four were determined as females and five as males. The determined mitochondrial haplogroups were H1b, H1c1, H1q, H6a1a, K1a4a1a+195, K1d1, T2b2b, U5a1a1e, and X2b4a. Thus, the majority of the Anglo-Saxon mitogenomes belong to haplogroup H, and amongst those, with one exception of H6a1a (KD002), to H1. H1 is the most common and widespread subclade of haplogroup H in Europe (for more details on haplogroup H, specifically H1 and H6, please refer to Appendix C).

Haplogroup U5a1a1e (KD035) is a subhaplogroup of U5a that corresponds to the end of the LGM, ∼18 kya (Malyarchuk et al., 2010b), and so far no ancient samples belonging to this subclade have been reported.

For haplogroup K1 the only reported ancient sample basal to K1d has been found in a Bell Beaker from the Netherlands (Olalde et al., 2018). K1a4a1 on the other hand, has been reported a total of 14 times, from Neolithic Scotland (Raschoille Cave, Oban, Argyll and Bute) and Spain (Lipson et al., 2017; Mathieson et al., 2018; Olalde et al., 2018), and Bronze Age Czech Republic, England (Amesbury Down, Wiltshire), Germany, Poland, Portugal, and Spain (Allentoft et al., 2015; Lipson et al., 2017; Knipper et al., 2017; Olalde et al., 2018).

H1b has only been found in one Bronze Age individual from Poland (Mathieson et al., 2018) and one individual from Medieval Alemmanic Germany (O'Sullivan et al., 2018). H1c has previously been reported in Neolithic England (Totty Pot, Cheddar, Somerset), Scotland (Distillery Cave, Oban, Argyll and Bute), and Sweden (Skoglund et al., 2014; Olalde et al., 2018), as well as Early and Late Bronze Age in England (Windmill Fields, Stockton-on-Tees, North Yorkshire), Germany and Latvia, respectively (Knipper et al., 2017; Mittnik et al., 2018; Olalde et al., 2018). H1q has been reported from Bell Beaker Spain (Olalde et al., 2018).

Mitochondrial haplogroup X2b4a has been found in two Bell Beaker males from France, who also both belong to the Y haplogroup/type R1b1a1a2a1a2

(Olalde et al., 2018), whereas KD034 belongs to a more derived Y-chromosome lineage of R1b1a1a2a1a2, namely R1b1a1a2a1a2c1a4b2c.
Y-chromosome haplogroup R1b lineages are associated with the Bronze Age migrations from the steppe, whereas haplogroup I1a is thought to have originated and spread from France (Rootsi et al., 2004). With the exception of two individuals (KD036, KD038) the analysed Anglo-Saxon males all belonged to R1b1a1a2 or one of its subhaplogroups (KD031, KD032, KD034, KD040 and KD041). Subhaplogroup I2a2b is one of the less frequent clades of Y-chromosome haplogroup I, which is an entirely European haplogroup (Rootsi et al., 2004).

8.4.5 Genome-wide analysis

In the PCAs, all analysed individuals from West Heslerton clustered within the variety of the European Late Neolithic/Bronze Age samples. Admixture analyses showed a more nuanced picture. The two Bronze Age individuals that had enough coverage to run admixture looked very similar to the European Late Neolithic/Bronze Age individuals. However, the SNP captured Anglo-Saxon individuals looked more similar to English and Scottish Late Bronze Age individuals, as well as to the post-Roman individuals from Worth Matravers, Dorset (Chapter 7). The two Iron Age individuals showed similar ancestral components as the English and Scottish Late Bronze Age individuals, however one looked more similar to the Iron Age individuals from the High Pasture Cave, Scotland and Knowe of Skea, Orkney.

Chapter 9

Archaeological evidence for facial mutilation in Anglo-Saxon Oakridge, Hampshire

9.1 Introduction

There is extensive literate relating to body mutilation, intentional or incidental. The evidence covers a wide time span, from dynastic Egypt up to modern times. Locations are also widespread, including the Far East, Asia, North and South America, the Middle East, Africa and Europe. Such bodily mutilation applies to the limb extremities, the head and especially the face. The human face is defined by the morphology of underlying bone, muscle and fat. However, soft tissues such as those forming the ears, nose, and lips, coupled with eye colour and hair colour serve to make each face distinct. They also facilitate social communication, allowing expression of emotions. The significance of normal facial appearance is also reflected in ancient codes of law. These introduced many forms of bodily mutilation as punishment for various crimes including amputation of one or both hands, or the slicing or cutting off of noses, ears and lips.

Whilst there is some archaeological evidence for intentional mutilation of limbs (Verano et al., 2000), there is limited archaeological evidence for facial mutilation, largely because it can affect soft tissues without leaving traces on the skeleton. Early excavations on a Romano-British site at Lowbury Hill, Berkshire, uncovered a skeleton supposedly with mutilated facial bones (Atkinson, 1916), but this may have been due to the effects of taphonomic change (Bennike, 2003). Possible evidence of scalping has been reported at the Romano-British sites of St Albans (Mays et al., 1996) and Wroxeter (Barker, 1981). The Wroxeter case appears to be an example of possible

frontal scalping, whilst the St Albans case is now considered to be the result of post-mortem defleshing, on account of the large number (> 90) of presumed cut marks over the whole skull surface. Here, genetic analysis was undertaken on an archaeological human skull that appeared to exhibit evidence of facial mutilation in the form of total removal of the nose and partial removal of the upper lip.

9.2 Materials

A skull was recovered during rescue excavations at a housing development at Oakridge, Basingstoke, England.

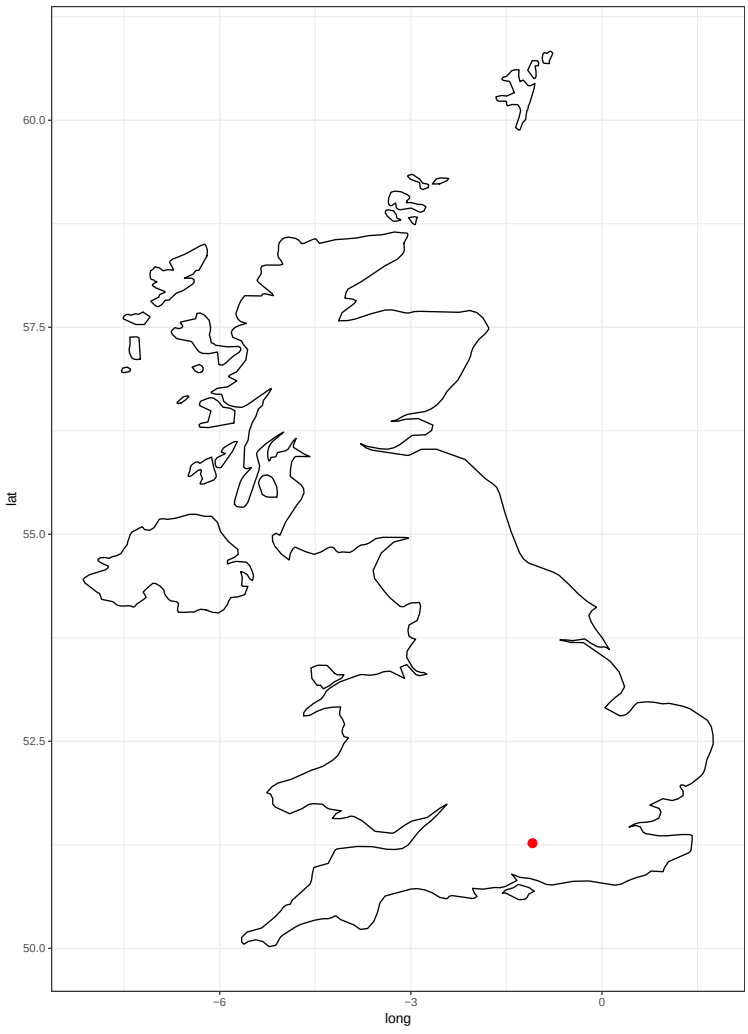

FIGURE 9.1: The location of the rescue excavation at Oakridge within the British Isles.

Only restricted archaeological intervention was permitted, although, after accidental discovery in a drainage pit, a Romano-British burial was fully excavated and recorded (Oliver, 1992). For some unknown reason, a skull recovered from the spoil heap was not analysed at the time, and it was not cleaned, so that the skull interior, the orbits, nasal cavity, and tooth sockets were completely filled with a very fine dark brown sandy silt. This was significant as it allowed the skull to be associated with a specific feature exposed in one of the drainage pit walls. The cleaned skull is shown in Figure 9.2.

9.3 Methods

The skull was assessed using standard osteological techniques to determine age at death and biological sex. The latter was tested by genetic analysis.
The left maxillary M1 was selected for ancient DNA analysis, in order to preserve the skull. Sample processing was undertaken at the Ancient DNA Facility of the University of Huddersfield under dedicated clean-room conditions and followed the standard protocol previously described in Chapter 2. The tips of the roots were cut off using a cutting saw attached to a hobby drill. A drill piece was used to powder the inside of the roots and the powder was collected for DNA extraction. DNA was extracted from approximately 150mg of the sample tooth powder produced, following the protocol by Yang et al. (1998) with modifications by MacHugh et al. (2000). Blank controls were included throughout extractions, library preparation and amplification steps to keep account for possible modern DNA contamination (Appendix D). Three dual-indexed next-generation sequencing libraries were constructed, quantified (Table 9.1) and pooled using the methods outlined in Chapter 2.

TABLE 9.1: DNA concentrations measured with the Qubit 3.0 Fluorometer.

ID	concentration in ng/µl
USER Blank	1.4
CE005.1	6.74
CE005.2	14
CE005.3	4.73
PCR Blank	0.882
Negative Control Library	0.992
PCR Blank	0.812

FASTQ files of the libraries were received with the indexes already trimmed off, a standard procedure of the sequencing service in Liverpool. The NGS reads were trimmed using cutadapt version 1.13 (Martin, 2011), allowing

FIGURE 9.2: Norma frontalis of cleaned skull showing well preserved frontal zone, with taphonomic surface degradation on the external surface of the left and right parietals, and the occipital. Figure reproduced from an original by Garrard Cole.

a minimum overlap of 1 bp between read and adapter (adapter sequence: AGATCGGAAGAGCACACGTCTGAACTCCAGTCAC), and discarding reads shorter than 30 bp. All further data processing steps followed the pipeline as described in Chapter 2. NGS libraries were sequenced on an Illumina

HiSeq2500 (1x100bp) by NBAF Liverpool. To assess the previously described anti-contamination measures, negative controls were introduced during each stage of sample processing as described in Appendix D. The two main patterns of typical ancient DNA post-mortem degradation, over-representation of C to T changes at the end of reads and short sequence length, were assessed using mapDamage 2.0 (Jónsson et al., 2013) and bamdamage (Malaspinas et al., 2014). Reads were only taken into account with a minimum mapping quality of 30. In order to detect possible modern mitochondrial contamination, schmutzi (Renaud et al., 2015) was used.
Genetic sex was determined using the software published by Skoglund et al. (2013), which calculates the ratio of reads aligning to the X and Y chromosome. The mitochondrial haplotype was determined by alignment of the sequence reads to the revised Cambridge Reference Sequence (rCRS; NC_012920.1; Andrews et al. (1999)), using BWA filtering (with -b and -q 30) and duplicate reads were removed. The mtDNA consensus sequence was called using Samtools mpileup, as in Martiniano et al. (2016). Haplofind (Vianello et al., 2013) was used to identify haplogroup defining mutations and assign the haplogroup of the sample. The mtDNA coverage was estimated using EAGER (Peltzer et al., 2016).
A powdered sample was extracted from the inner table of the occipital bone in order to determine a radiocarbon date for the specimen. This was processed using the standard Oxford Laboratory protocol (Ramsey et al., 2002; Ramsey et al., 2004b; Ramsey et al., 2004a), and the resultant data was calibrated using OxCal v4.1.7 (Ramsey et al., 2010). In addition, the same left maxillary M1 that had been selected for the ancient DNA analyses was also sampled for strontium, carbon, nitrogen and oxygen stable isotopic analyses.

9.4 Results

The skull was clearly that of a young person, as the maxillary third molars were just erupting from their crypts. The only *in situ* erupted tooth was the left first maxillary molar, all other sockets were present but with the relevant teeth lost post mortem. These features in combination indicate that the individual died at a developmental age of about 18 years. Given the young age of the individual and the absence of the pelvis, it was not possible to determine the sex of the individual with any confidence. The skull had rounded features, with prominent frontal bossing and a gracile zygomatic arch, which

is typical of females, but young males may also exhibit such features prior to full expression of sexual dimorphic traits.

There was a linear cut on the medial left frontal bone. The cut was found to have a v-shaped base, and was oriented obliquely to the right when facing the skull. It had clearly been made peri-mortem. Secondly, the removal of sediment revealed exposed trabecular bone at the base of the nasal aperture, cutting through the front of the maxillary central incisor sockets. The anterior nasal spine was also missing. The trabecular zone was surrounded by a margin of sharply defined cortical bone, especially at the base of the nasal aperture. The lower left and right lateral margins of nasal aperture were truncated. Overall there appeared to be one or more straight cuts through the nasal margin from mid way up the nasal aperture through the anterior nasal spine to the prosthion. Close examination of the lateral aspect revealed a sharp v-shaped nick on the left side of the nasal aperture with the cut through the lips at a slightly different angle to that through the nasal margins. This suggests that at least two cuts were made to inflict the injuries (see Figure 9.3).

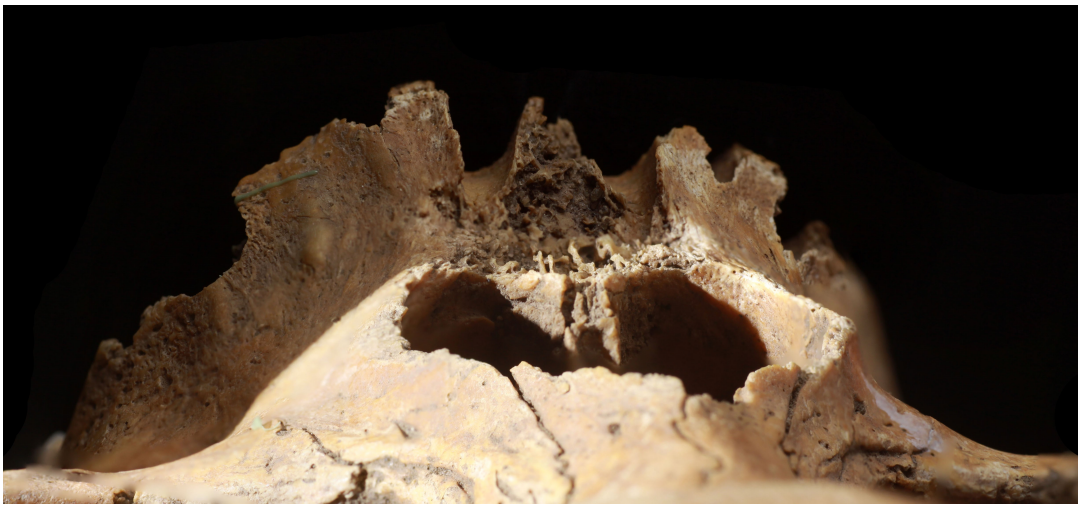

FIGURE 9.3: View along nasal aperture showing linearity of cut on the base and right side and sharp nicks around the apex of the left central incisor.

9.4.1 Sequencing results

Sequencing results are displayed in Table 9.2.

TABLE 9.2: Summary of sequencing results.

ID	CE005
Genome coverage	1.0143x
Genome std coverage	3.3005x
Mean mapping quality	12.029
GC content in %	45.61
No of reads	65698100
No of mapped reads	65698100
No of mapped bases	3.26E+09
Duplication rate in %	2.67

9.4.2 Radiocarbon dating

The uncalibrated radiocarbon date (OxA-26646) was determined to be 1173 ± 24 years bp and the calibrated 2σ date range was found to lie between 776-899 (87.3%) and 920-946 (8.1%) (see Figure 9.4).

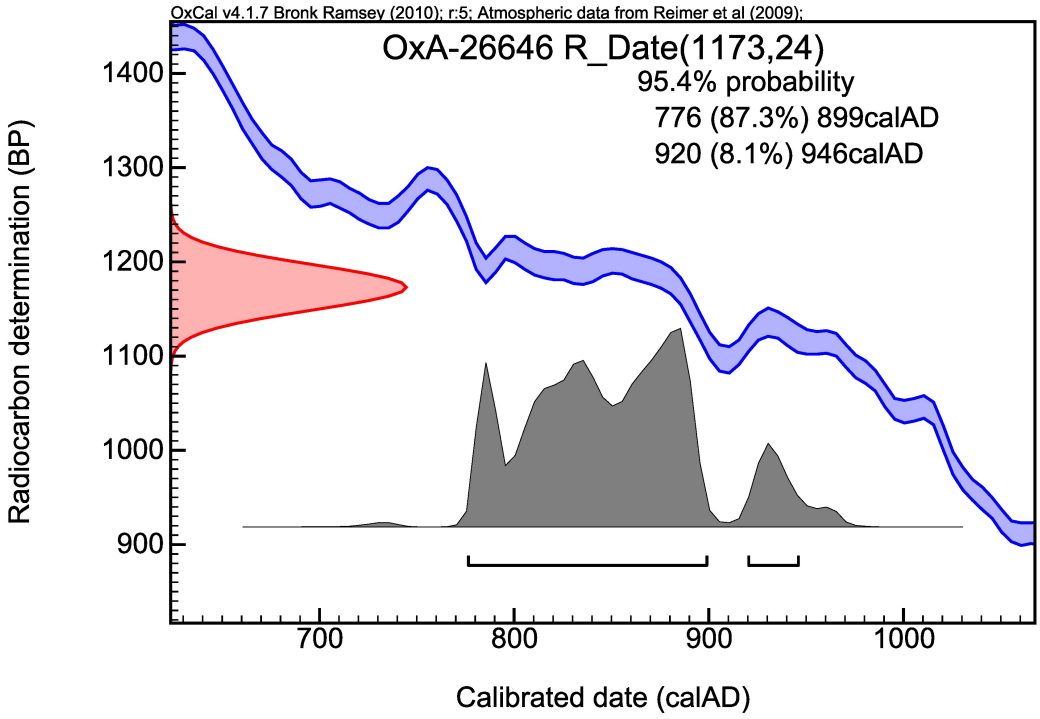

FIGURE 9.4: Calibrated radiocarbon dates based on an uncalibrated date of 1173 +/- 24 years bp.

9.4.3 Dietary stable isotope analysis

The collagen prepared from the tooth dentine gave a C/N ratio of 3.1, suggesting that the collagen was well preserved and likely to give a good measure of the in-vivo dietary carbon and nitrogen stable isotopic values (Van Klinken, 1999). The δ^{15}N value was 11.71‰ relative to AIR, and the δ^{13}C value was -19.03‰ relative to VPDB, both with error of ± 0.1‰. The δ^{13}Cc value was -12.78‰ ± 0.01 and the δ^{18}Oc value was -6.47 ± 0.02 both relative to VPDB. The $^{87/86}$Sr ratio was 0.710279 ± 0.000014 (Figure 9.5).

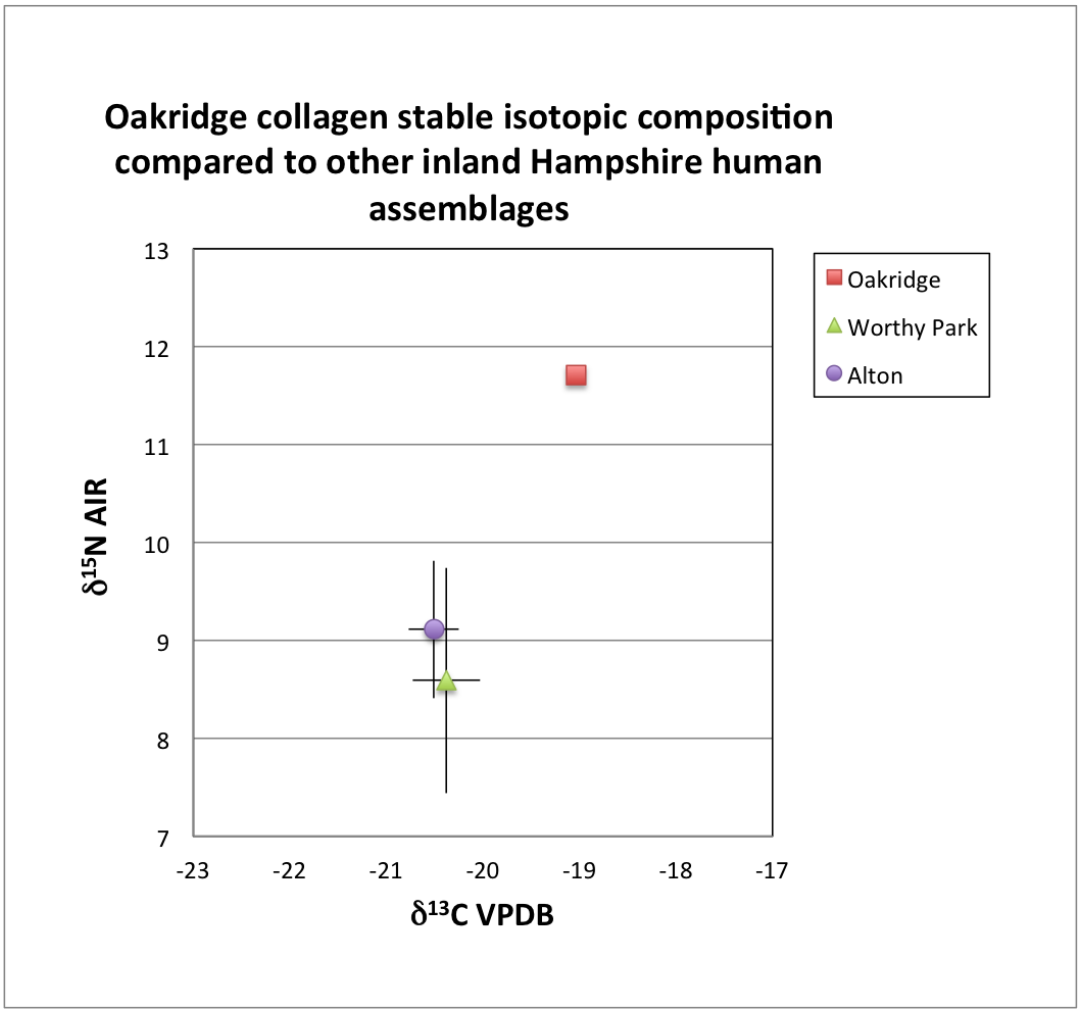

FIGURE 9.5: Dietary stable isotope estimates of the Oakridge individual in comparison to dietary stable isotope values of individuals from Worthy Park and Alton.

9.4.4 DNA damage and contamination estimation

The endogenous DNA content retrieved from the sample was 70.08%. A misincorporation pattern typical for aDNA was observed, with reads showing

an increase in C to T and G to A transitions towards the 5′ and 3′ ends, characteristic changes of aDNA molecules (Briggs et al., 2007; Brotherton et al., 2007). Estimates of mitochondrial contamination were very low, at a range from 0.12-0.17%.

9.4.5 Mitochondrial genome analysis

The individual was determined as female. The mitochondrial haplogroup was determined to be H3g1a (Results in Table 9.3).

TABLE 9.3: Summary of mitochondrial genome coverage, haplogroup assignment and haplotype of the Oakridge sample

Sample ID	Coverage	Haplogroup	Haplotype
CE005	42.2919x	H3g1a	152C 263G 750G 1438G 2523Y 3992T 4135C 4418C 4769G 6776C 8251A 8860G 10754C 15326G 15377G 16519C

The phylogenetic tree of mitochondrial haplogroup H3 was reconstructed for an analysis described in Appendix C. The branch of H3g1 was reconstructed using published data (Figure 9.6).

9.5 Discussion

9.5.1 Dating

The skull gave a date of late 9th century AD (between cal. AD 767 and 970). This date range covers that of a documented battle, the Battle of Basing, which occurred between Danes and local Saxons on the 22nd of January AD 871 (King et al., 2016). It is possible that the victim could either have been punished after being captured by the opposing side, or punished for collaborating with the enemy.

9.5.2 Stable isotope analysis

The calculated δ^{18}Ow value for the tooth enamel was -9.22‰ SMOW, whereas modern ground water δ^{18}O values for the area where the sample was found are around -7‰ SMOW (Darling et al., 2003). The conversion of measured

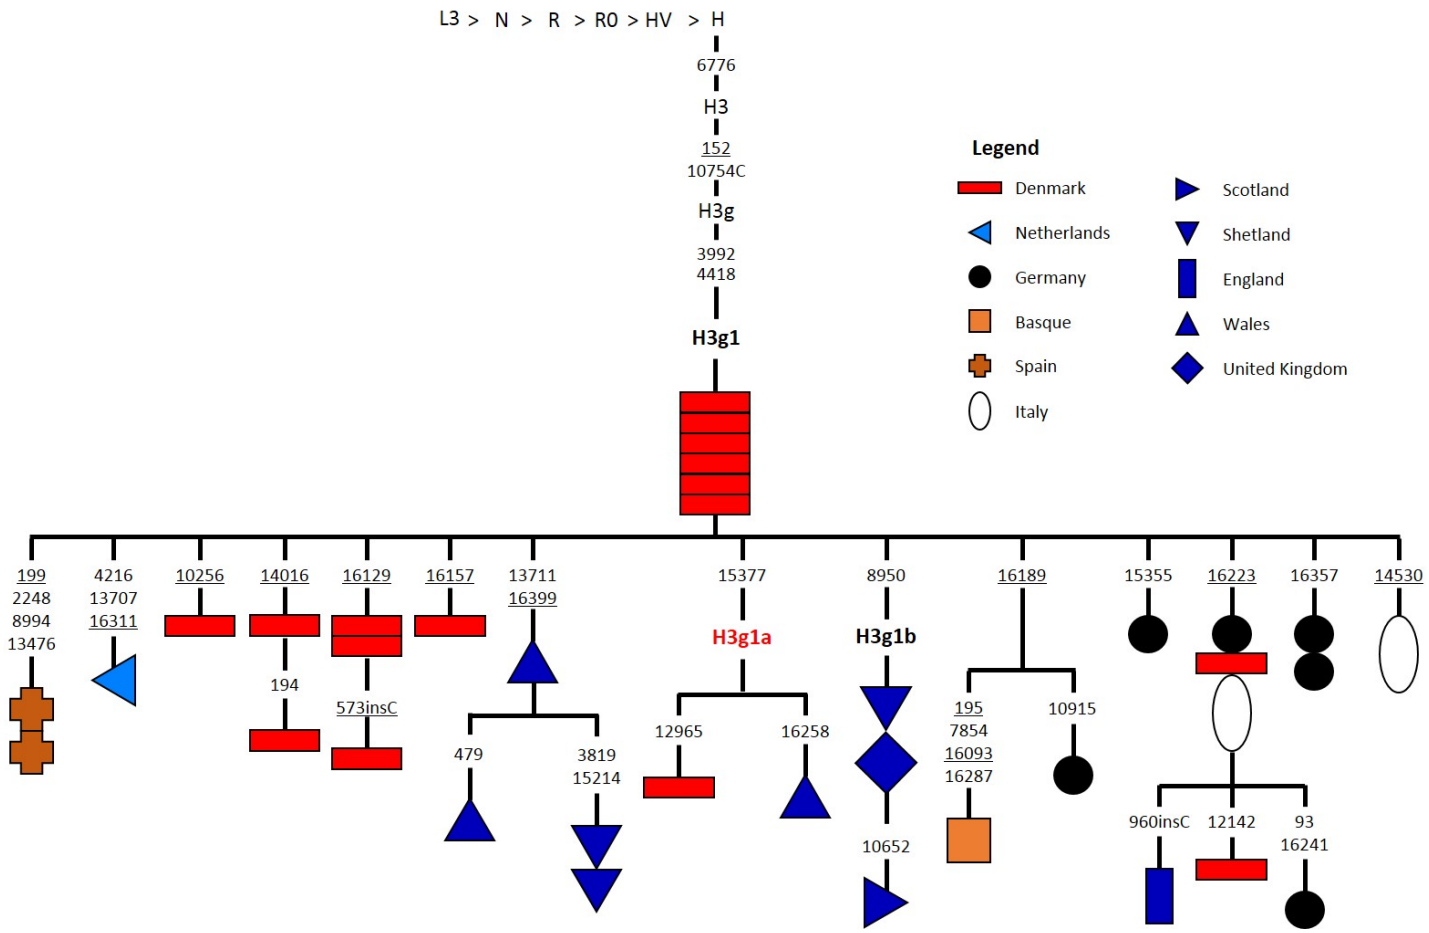

FIGURE 9.6: Schematic of the branch of H3g1 within the phylogenetic tree of H3. Samples originating in the British Isles are coloured in dark blue. The reconstruction of the phylogenetic tree only shows modern samples.

carbonate values to theoretical phosphate values and, thence to probable water values, is fraught with uncertainty (see Pollard et al. (2011) for discussion); however, in this instance, there appears to be a considerable difference between the likely drinking water composition at the time of tooth mineralisation, and the modern ground water composition at the location where the sample was excavated, suggesting that this individual was likely to be non-local. The strontium isotopic composition of tooth enamel is strongly influenced by the underlying geology at the time of tooth mineralisation (Chenery et al., 2010). The tooth enamel $^{87/86}$Sr ratio value measured from the Oakridge individual was 0.710279 ± 0.000014, which falls well outside of the range for the local chalk and just outside of the range for the nearby Tertiary sediments. This also suggests that this individual was not local; that is, they did not spend their early years, during the time of M1 mineralisation, in the immediate area around Basingstoke.

The carbon and nitrogen stable isotopic results, of δ^{13}C -19.03‰ (VPDB) and δ^{15}N of 11.71‰ (AIR) respectively, suggest a predominantly terrestrial diet with a minor marine protein component. However, in the absence of any associated faunal remains from the same location, it is impossible to give an absolute indication of what these values might mean in terms of the relative amounts of plant versus terrestrial animal versus marine protein consumed. Comparable local dietary isotopic data sets are available from Worthy Park near Winchester, Hampshire (ca. 25 kilometres southwest of Basingstoke), and Alton, Hampshire (ca. 15 kilometres to the southeast) (Hull, 2008). These sites have yielded mean δ^{13}C values for adult human bone collagen of -20.38‰ and -20.51‰, with a standard deviation of 0.35 (n = 26) and 0.26 (n = 25), respectively, and mean δ^{15}N values of 8.59‰ and 9.11‰, with a standard deviation of 1.15 (n = 26) and 0.70 (n = 25), respectively.

By comparison, the values for the Oakridge individual are higher in both δ^{13}C and δ^{15}N than the means reported for the Worthy Park and Alton Saxon burials (Figure 9.5). This suggests that the diet of the Oakridge individual was slightly anomalous compared to the average diet that might be expected for inland Hampshire in middle Saxon times, with the less negative value for δ^{13}C and the more positive value for δ^{15}N suggesting more of a marine component in the Oakridge diet than usual for inland Hampshire. Taken alongside the strontium and oxygen isotopic data, the dietary stable isotopic information is also compatible with a non-local origin for this individual.

9.5.3 Mutilation

The skeletal remains consisted of the partial skull of a juvenile individual exhibiting dramatic trauma. For males, this is most likely to have happened as a result of fighting. For females, it was a most likely a punishment for (alleged) adultery. As morphological indicators were unable to identify sex (mainly due to partial remains and young age of the individual), the sex was determined genetically as being from a female. If she was involved with the Battle of Basing, it is possible that she was punished for collaborating with the enemy. The battle option also raises the question of origins, Dane or Saxon? Unfortunately, it was not possible to analyse which of these populations she belonged to as Danish and Saxon people are very similar genetically, as the genomic coverage was too low. As the individual was female, then it seems more probable that she was a Saxon, as it would be less likely to have a 'foreign' female fighting in a battle.

9.5.4 Maternal lineage

She had mitochondrial haplogroup H3g1. Today, over 40% of all maternal lineages in Europe belong to haplogroup H. H3 has high frequency in modern-day Spain (Achilli et al., 2004) and in the Western Isles of Scotland (Brotherton et al., 2013), and is also present in the middle Neolithic period (including at Orkney) and the Bell Beaker culture in Europe (Brotherton et al., 2013; Olalde et al., 2018). H3g1 is generally seen in modern-day northwestern European people, with the root comprising solely of people from Denmark (n = 6; Figure 7), although English, Shetland, Scottish, Welsh, German and Dutch people also group within the H3g1 clade. The Oakridge sample, with a mitochondrial haplotype of H3g1a, groups together with modern people from Denmark and Wales (n = 1 for each), so, unfortunately, it is not possible to say anything about the origin of the female based on her maternal lineage.

9.6 Conclusions

This chapter presents evidence of facial mutilation to a young adult female around 18 years of age. She was probably not local to the Hampshire area, but perhaps was from northern England or southern Scandinavia. Since the physical evidence was observed only from the skull, and there is no evidence

for or against the infliction of injuries elsewhere on the body, the exact circumstances behind the infliction of the mutilating wounds is not known. The limited 'rescue' excavation means that there is no evidence whether the body was even deposited along with the skull. The injuries present are consistent with documented punishment of females for adultery. Based on historical evidence, other possible options include a brutal attack arising from jealousy, or abuse of a hostage. Irrespective of the circumstances behind the incident, this case appears to be the first archaeological evidence for this form of brutal mutilation in Anglo-Saxon England.

Chapter 10

Discussion

The following is a brief overall discussion of the findings reported in this thesis, as more detailed discussions are included in each chapter. A total of 77 bone and teeth samples, covering the Neolithic, Bronze Age, Iron Age, Pictish, post-Roman/Anglo-Saxon, and Viking periods (Table 10.1), were processed to investigate human dispersal by means of the maternal and paternal lineages of descent, as well as using autosomal data for admixture and kinship analyses. The samples analysed in the present study have given new insights into the genetic makeup of the British population at various time periods, and allowed a direct comparison across periods and locations (Figure 10.1).

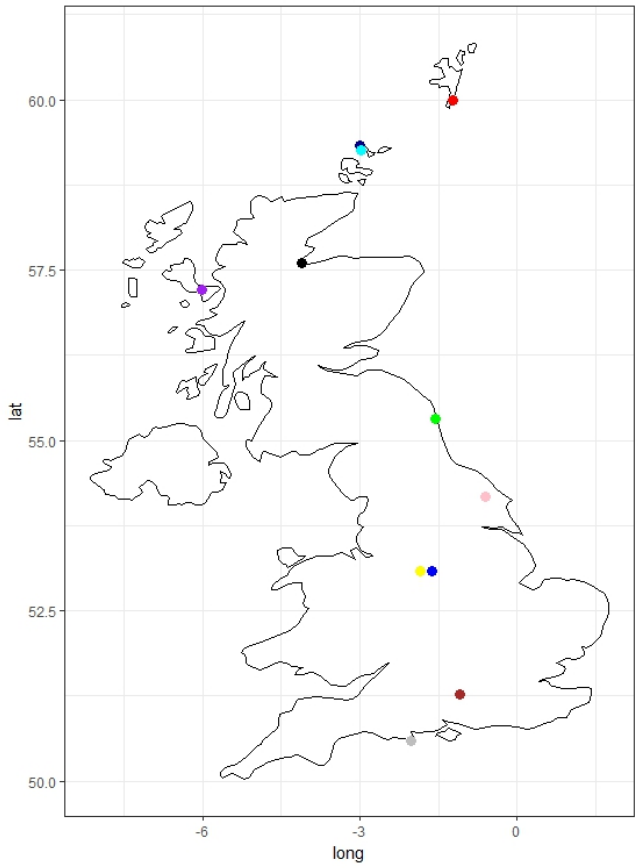

FIGURE 10.1: All sampling sites within the British Isles. 10.1 Genome-wide analysis

The distinctive geographic position of the British Isles at the north-western extreme of Europe led to later arrival times of agriculture and following cultural packages, such as the Bell Beaker culture, compared to continental Europe. With these cultural changes, major population replacements have been reported for the Mesolithic/Neolithic transition (Brace et al., 2018) and the arrival of the Bell Beakers (Olalde et al., 2018). Nevertheless, it is also clear that the population in the Bronze Age was not exactly the same as it is today (Olalde et al., 2018). Further investigations, especially at the transitions between the Bronze Age and Iron Age, Iron Age to Roman era, and Roman era to the Anglo-Saxon and Viking invasions, are required in order to more fully understand population turnover and admixture in the British Isles through time. The only ancient genome-wide data from these later, post-Bronze Age, periods are studies of a Roman cemetery in York (Martiniano et al., 2016) and Iron Age and Anglo-Saxon sites in south-east England (Schiffels et al., 2016).
ADMIXTURE and PCA plots were calculated using the protocol in Chapter 2, and the resulting figures are shown in Figure 10.2 and Figure 10.3. Only samples that had greater than 10,000 SNPs were included in this analysis, so the total number of individuals was reduced to 55.
Due to the fact that the sequencing data of the recently sequenced Mesolithic and Neolithic individuals of the British Isles (Brace et al., 2018) are not yet publicly available, no direct comparison between my samples and these individuals was possible. However, comparing the Neolithic individual from Strathglebe, Isle of Skye (KD026), with the available published data (Lazaridis et al., 2016; Olalde et al., 2018) and the additional Bronze Age individuals from this study, the greatest similarity of ancestral components appears between the Strathglebe individual and European Middle Neolithic individuals, all of which lack the Caucasus hunter-gatherer Steppe component that is clearly seen in the Bronze Age individuals.
Interestingly, the Bell Beaker individual from Low Hauxley (KD070), which otherwise showed genetic similarity to the Late Neolithic and Bronze Age individuals from Czech Republic, Denmark, England, Estonia, Germany, Hungary, Poland, Scotland, and Sweden (Lazaridis et al., 2016; Olalde et al., 2018), also exhibits a small proportion of North African ancestry (Figure 10.2). As the overall genome coverage of this sample was low, and thus the North African ancestry might conceivably be artificial, this result needs to be treated with caution. However, this interesting result could be verified by additional

sequencing to higher depth and repetitive runs of ADMIXTURE analysis.
Unfortunately, the genome coverage of the Iron Age individual from Sandwick, Unst, Shetland (KD073), was too low to allow any autosomal comparison with the other individuals of this study or the published modern and ancient data. In the PCA, the Neolithic individual from Carsington Pasture Cave in Derbyshire (CE001) (Appendix I) and Strathglebe on Skye (KD026) cluster closest together within the distribution of the European Middle Neolithic individuals, whereas the two Iron Age individuals (CE003 and CE004) cluster with Bronze Age individuals from the Links of Noltland and post-Roman individuals from Worth Matravers (Figure 10.3).
An individual from Strathglebe (KD027) was dated to ∼3,494-3,104 cal. BC, which corresponds to the Scottish Early Neolithic. Together with the Neolithic individual from Carsington Pasture Cave, Derbyshire (CE001), the Scottish Neolithic individual that had enough coverage to be examined in more depth (KD026) showed greatest similarities with published European Middle Neolithic individuals. Comparing the ancestral components of the Neolithic data, which comprise the two individuals presented here, as well as samples from Cassidy et al. (2016) and Olalde et al. (2018), with the Beaker and Bronze Age periods, the arrival of a new population with Steppe ancestry in Europe is evident in the Bronze Age. The impact of this Steppe component is especially strong in the Bell Beaker individual from Low Hauxley (KD070), Bronze Age individuals from the Links of Noltland (KD006, KD044-045, KD047, KD049-050, KD055, KD057-058, KD060-065, and KD067) and West Heslerton (KD003 and KD041), Iron Age individuals from Knowe of Skea (KD004, KD042 and KD043), most of the post-Roman individuals from Dorset (KD007-009, KD011-014 and KD016-022), the Yorkshire Anglo-Saxons (KD002 and KD033-038), and the Oakridge individual (CE005). One of the Iron Age individuals from West Heslerton has an exceptionally large Steppe component (KD072), whereas the Pictish Rosemarkie individual (KD001) had a comparably small portion of this ancestral component.
The individuals from the post-Roman cemetery at Worth Matravers in Dorset showed most similar proportions of ancestral components to modern northern Europeans (Figure 10.2). In general, these data showed a difference in the genetic composition during post-Roman times in England, with one outlier individual (KD010) having ∼50% North African or Near Eastern ancestry, which is shown in a PCA with modern samples (Figure 10.4).
The autosomal analysis of the Iron Age High Pasture Cave (KD005) and the

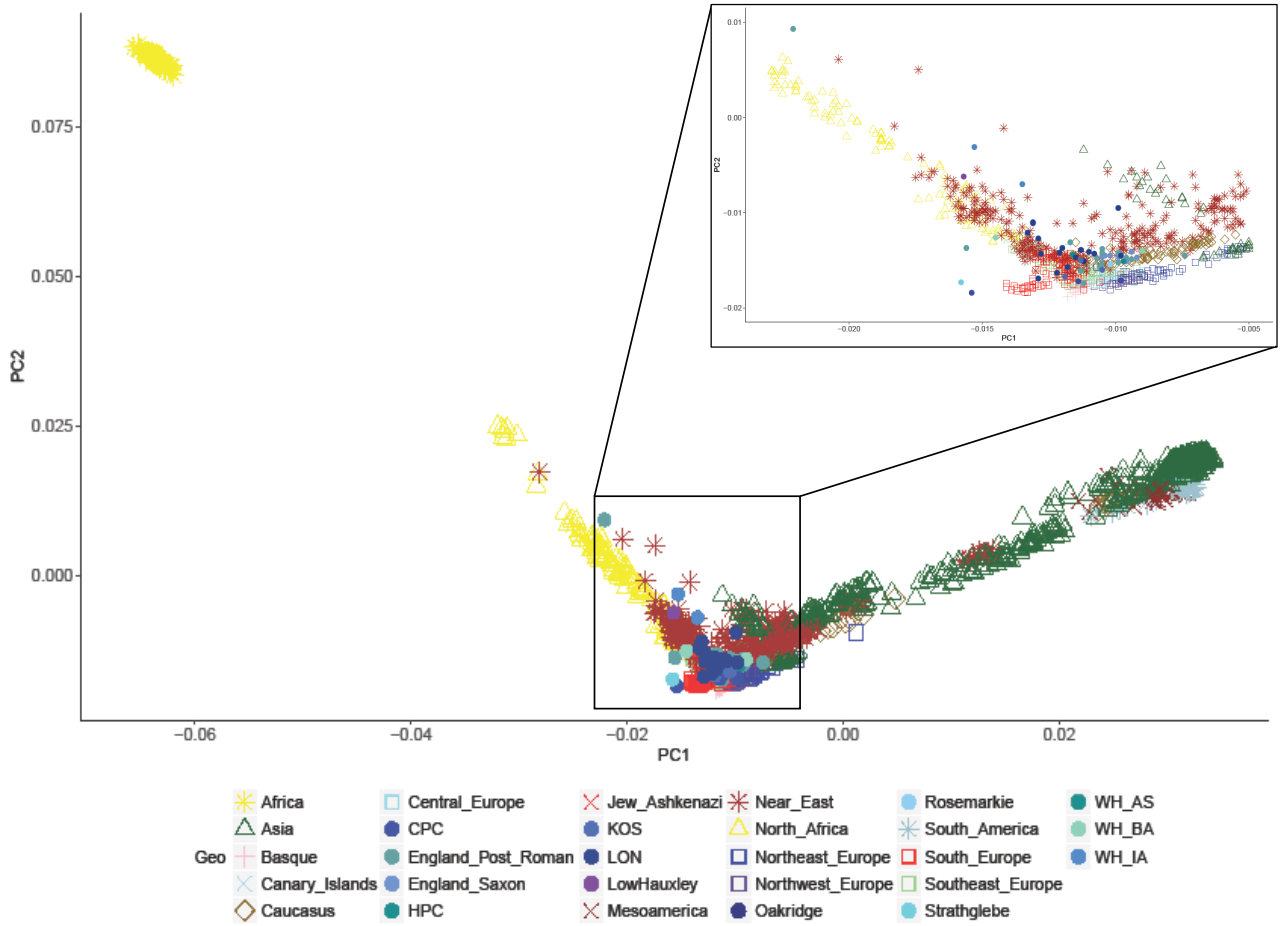

FIGURE 10.4: PCA of all analysed individuals with >10,000 overlapping SNPs projected on top of the published modern data of Lazaridis et al. (2016).

Pictish individual from Rosemarkie Cave (KD001) showed a strong similarity in the proportion of ancestral populations with the Late Neolithic/Bronze Age populations of Europe. The obvious lack of genetic influence through the Roman Empire in Rosemarkie Man can be explained by the general low level of immigration into Scotland at this time. Further studies of the Scottish populations, especially during the Iron Age and adjacent periods, are needed to understand possible differences in genetic admixture between the northern (Scottish, Pictish) and southern (Briton, Anglo-Saxon) populations of the British Isles.

The Anglo-Saxon individuals analysed from the cemetery in West Heslerton, North Yorkshire, were most similar to British Middle Bronze Age individuals and the post-Roman individuals from Worth Matravers, Dorset (Figure 10.2). However, when compared to the English Saxon individuals, the sample from Oakridge, Hampshire (CE005), had similar ancestral proportions as the Iron Age sample from High Pasture Cave and the Pictish Rosemarkie Man, both from Scotland. As archaeologists suspected the individual to be either Viking or Anglo-Saxon, this result requires further investigation and a more detailed STRUCTURE-like analysis, and the addition of samples from Scandinavia may allow a more detailed genetic analysis of whether this young mutilated female was of Saxon or Scandinavian ancestry. The strong similarity between modern north-western and central European populations would make a fineSTRUCTURE (Leslie et al., 2015) approach necessary in order to identify possible differences and give an indication of the origin of the Oakridge individual.

Overall, all ADMIXTURE results presented in this thesis need to be treated with caution in order to avoid over-interpretation of the results, such as, for example, the possible North African component found in the Bell Beaker individual from Low Hauxley. All shot-gun sequenced samples presented have a very low coverage compared to most published ancient data, and the analysis might be skewed. Generally, I found that samples with a minimum of 10,000 SNPs behave as expected when plotted in a PCA or in ADMIXTURE runs. However, repetitive runs and further sequencing are necessary to rule out incorrect clustering and any skewing effects due to the low coverage data (Lawson et al., 2018).

10.2 Mitochondrial DNA haplogroup frequencies

An increase in haplogroup H over time can be observed when comparing the overall mitochondrial haplogroup frequencies across different time periods in the British Isles. Already between the Bronze and Iron Age, the frequency of haplogroup H has increased to similar levels as those seen in the present day population.
Of all published ancient mitochondrial genomes from the British Isles and Ireland, 68 date to the Neolithic. When including the individuals from this study (n = 7), the mitochondrial haplogroup frequency composition consists of 31% of K1, 13% of U5b and J1, 10% of T2, 8% of H1, 6% each of H5 and U5a, and 3% of X2. Basal H, H3, H4, HV, HV0, U2, U8, V, and W1 have each a frequency of 1% (Figure 10.5). Overall, haplogroup H accounts for 17% in this dataset, of which the majority were found in Scotland (n=12), rather than England (n=1).

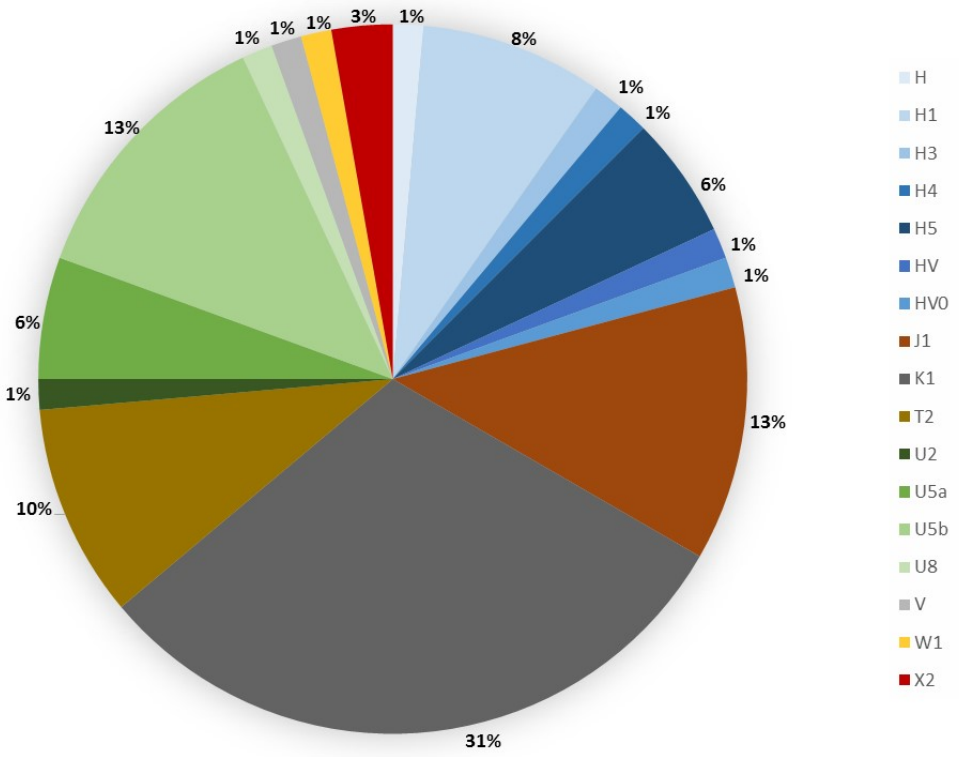

FIGURE 10.5: Mitochondrial DNA haplogroup frequencies of published Neolithic individuals from the British Isles and those reported in this study.

132 individuals date to the Beaker period and Bronze Age, of which 107 are published complete mitogenomes and 25 are from this study. The highest frequency during the Bronze Age in Britain is haplogroup T2 (16%), followed by U5b (13%), K1 (11%), H1 (9%), J1 (8%), U5a (6%), H5 and H39 (each 4%),

H, H2, H3, H6, I2, K2, U4, V10, W1, and X2 (each 2%), and H13, H15, H4, H5'36, H58, HV0, I3, I4, J2, N1, R1, T1, U2, and V (each 1%) (Figure 10.6). The overall frequency of haplogroup H during the Bronze Age is 30%.

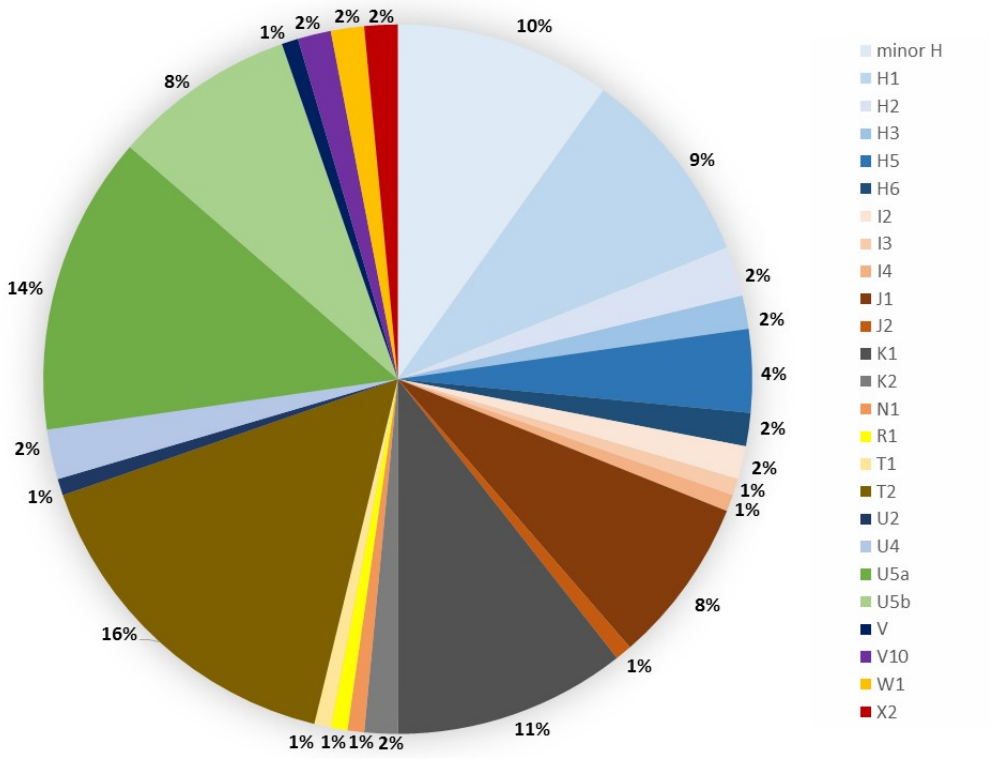

FIGURE 10.6: Mitochondrial DNA haplogroup frequencies of published Bronze Age individuals from the British Isles and those reported in this study.

The published mitochondrial genome dataset consists of four genomes dating to the Iron Age. Including the 12 genomes of this study, the mitochondrial frequencies during the Iron Age in Britain are as follows: H1 38%, J1 19%, H7 13%, and H10, K1, U2, U5 and X2 each 6% (Figure 10.7). The overall frequency of haplogroup H during the Iron Age is 57%, although clearly with a large sampling error.

In the Anglo-Saxon subset, consisting of eight published and 16 newly reported post-Roman and 10 Anglo-Saxon mitogenomes, H1 has a frequency of 26.5%, K1 and T2 of each 15%, HV of 11.8%, H2, U5a and U5b of each 5.9%, and H3, H5, H6, H11 and X2 of each 3% (Figure 10.8). In the Anglo-Saxon data, haplogroup H has an overall frequency of 44%.

Comparing the haplogroup frequencies across the different time periods, the most prominent difference is the increasing frequency of haplogroup H. While K1 was the most frequent haplogroup in the Neolithic, with J1, T2 and U5b also being relatively frequent, mtDNA haplogroups H1 and H5 accounted for only a small fraction of the mitochondrial haplogroups recovered

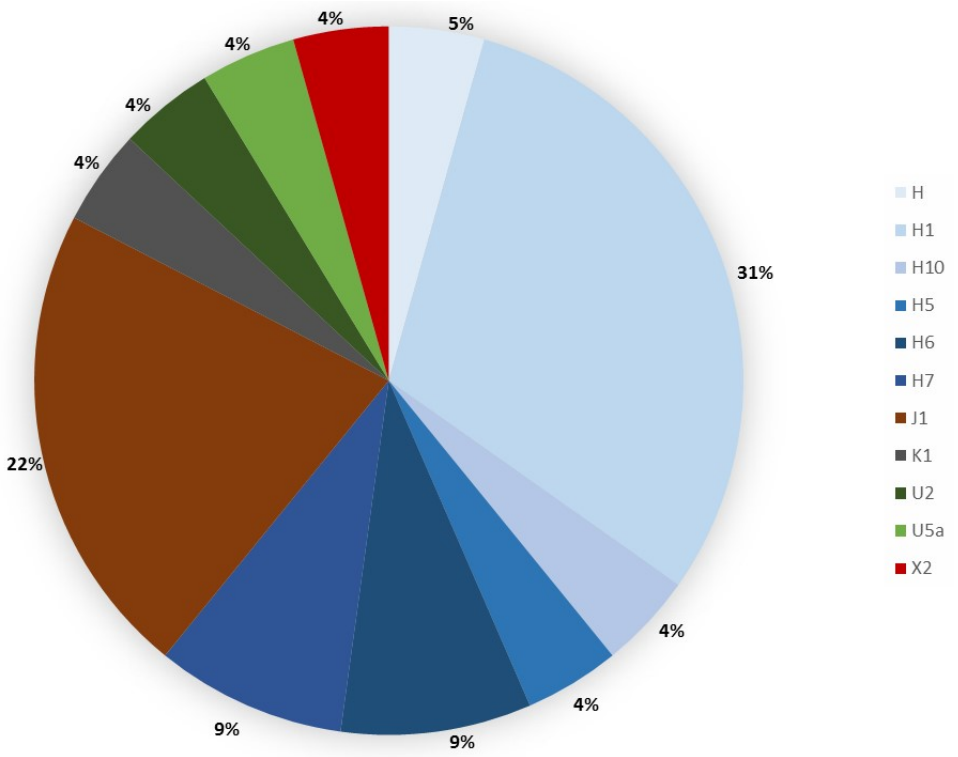

FIGURE 10.7: Mitochondrial DNA haplogroup frequencies of published Iron Age individuals from the British Isles and those reported in this study.

during this time. The arrival of the Bronze Age migrations to the British Isles changed the overall frequency of haplogroup H, with H1 more frequent and the appearance of more subhaplogroups of H. Subhaplogroups of I (I2, I3 and I4), which have not been seen in the Neolithic dataset, were also present and the frequency of K1 drastically decreased from 31% in the British Neolithic to 11% in the British Bronze Age. The frequency of U5b decreased, whilst the presence of U5a increased from 6% to 14%, and the frequency of T2 increased from 10% to 16%.

Haplogroup H1 accounted for almost 40% of the overall haplogroup frequencies in the British Iron Age, although the small sample size should be taken into consideration. The frequency of K1 decreased even more to only 6%, compared to 31% during the Neolithic. Similar to H1, J1 increased in frequency during the Iron Age as well, whereas U5a, which peaked during the Bronze Age, decreased back to its Neolithic frequency.

The mtDNA haplogroup H frequency of the British Anglo-Saxon period was equal to that of the modern British population with 44%. Haplogroup HV* showed an increased frequency of 12%, compared to only 1% during the Neolithic. K1 and T2 together accounted for almost 30%, and U5a and U5b each had a frequency of 6%, which for U5a was similar to the frequency during the

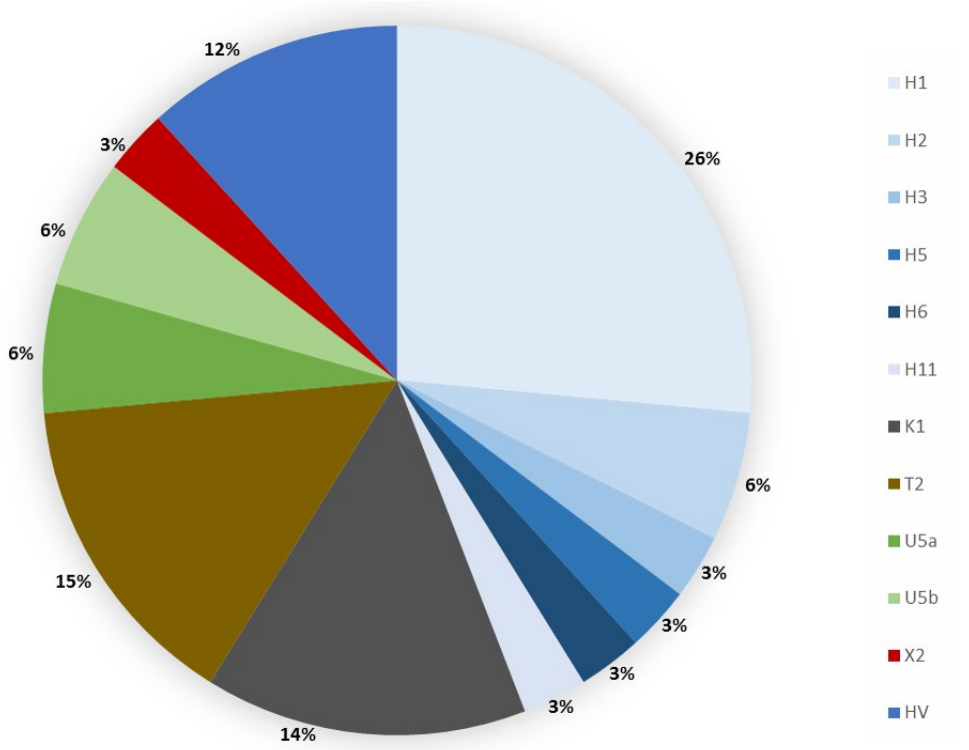

FIGURE 10.8: Mitochondrial DNA haplogroup frequencies of published Anglo-Saxon individuals from the British Isles and those reported in this study, including the post-Roman data.

Iron Age. Due to the rather small Iron Age sample size, it is likely that the presence of U5b in the Iron Age has not yet been detected. Further analysis of Iron Age individuals would be necessary to gain a more complete picture. Generally, U5b is a marker for Late Glacial expansions from the south-west European glacial refuge and very common in the modern Saami population (Silva et al., 2019), and I report here the presence of a subclade of U5b, namely U5b2c, in British Early Neolithic Strathglebe sample.

Mitochondrial haplogroup H, especially H1 and H3 (detailed discussion in Appendix C) from Copper Age Iberia, has been found in high frequency in early Bell Beaker burials in central Europe, alongside Y-chromosome haplogroup R1b. While Y haplogroup R1b spread to Britain during the Bell Beaker and Bronze Age migrations, mtDNA haplogroup H had clearly already arrived with the Neolithic expansions, suggesting a mixed, sex-biased ancestry of female farming lineages from the Mediterranean and male pastoralist lineages of the Steppe (Silva et al., 2019).

10.3 Y-chromosome haplogroup frequencies

As the frequency of mtDNA haplogroup H increased with the Bronze Age migrations in Europe, a similar pattern can be observed for Y-chromosome haplogroup R1b. Overall, the Y-chromosome haplogroup could be assigned to the majority of samples classified genetically as males, with the total number being 33 individuals. All haplogroups presented throughout this study should be understood as predictions only, as all samples had a very low genome coverage and so are likely missing a large number of haplogroup-identifying SNPs (as can be seen in more detail in the individual tables of recovered derived SNPs per male individual in Appendix G). However, the more resolved predicted haplogroups gave a good indication of the overall haplogroup frequencies across the analysed different time periods.

The available Y-chromosome data from the Neolithic consists of 34 published samples (Olalde et al., 2018), and one individual from Strathglebe (KD026) and one from Carsington Pasture Cave (CE001). Over 80% of all individuals belonged to Y-chromosome haplogroup I2 or its subclades (I2a1b accounts for 20%, I2a1b1 for 17.1%, I2a2 for 8.6%, I2a2a for 11.4%, I2a2a1 for 5.7%, I2a2a1a1a for 8.6%, I2a2a1a1a2 for 5.7% and I2a2a1b for 2.9% of the overall Neolithic dataset) (Figure 10.9). 14.3% belonged to unclassified haplogroup I, and one individual was classified as belonging to haplogroup CT (I5374 from Olalde et al. (2018)). However, as the individual predicted to belong to Y-chromosome haplogroup CT had an extremely low coverage, he should be disregarded from conclusions.

The Y-chromosome data from the Bronze Age in Britain contained 59 published (Olalde et al., 2018) and 11 newly reported individuals, nine from the Links of Noltland (KD006, KD045, KD047, KD049, KD057, KD059, KD060, KD061 and KD064) and two from West Heslerton (KD040 and KD041). The vast majority of individuals belonged to subclades of R1b1a1a2 ($\sim$75%). Haplogroups I and I2a1 each have a frequency of $\sim$5.8%, haplogroups I2a2 and R1b1a2a1a each have a frequency of $\sim$4.3%, and haplogroups F, R, and R1 (all from published data) each have a frequency of $\sim$1.4% (Figure 10.10). Again the samples with the predicted haplogroups F, R and R1 had very low Y-chromosome coverage and could thus not be further resolved. These percentages should merely be seen as an indication of presence of a specific haplogroup. The prediction of F is probably incorrect, as haplogroup F for example is basal to both haplogroups I and R.

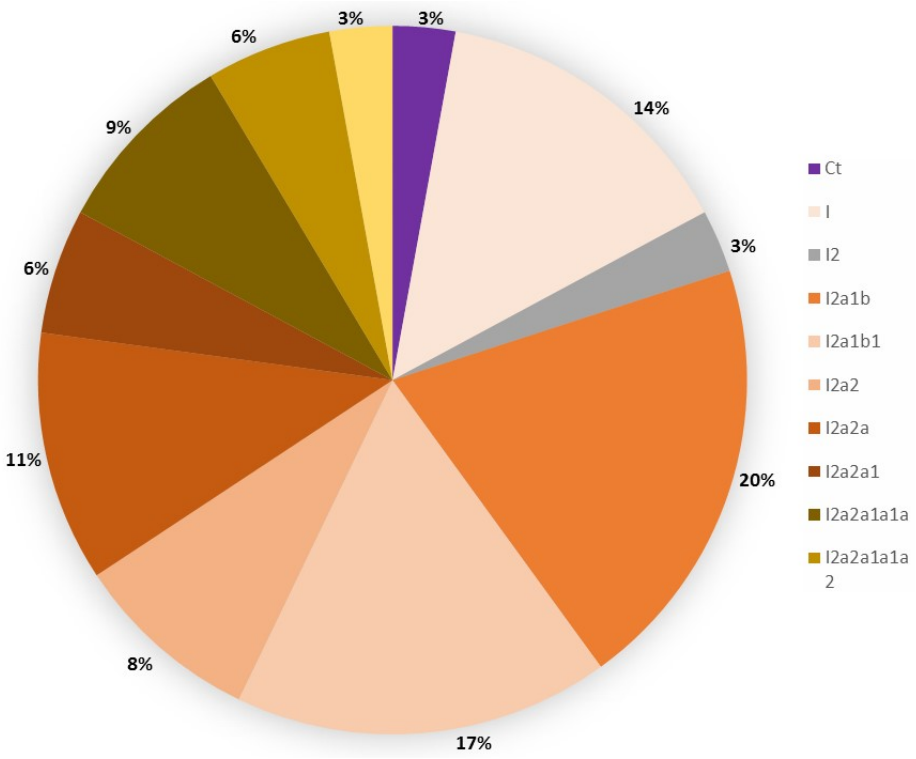

FIGURE 10.9: Y-chromosome haplogroup frequencies of published Neolithic individuals from the British Isles and those reported in this study.

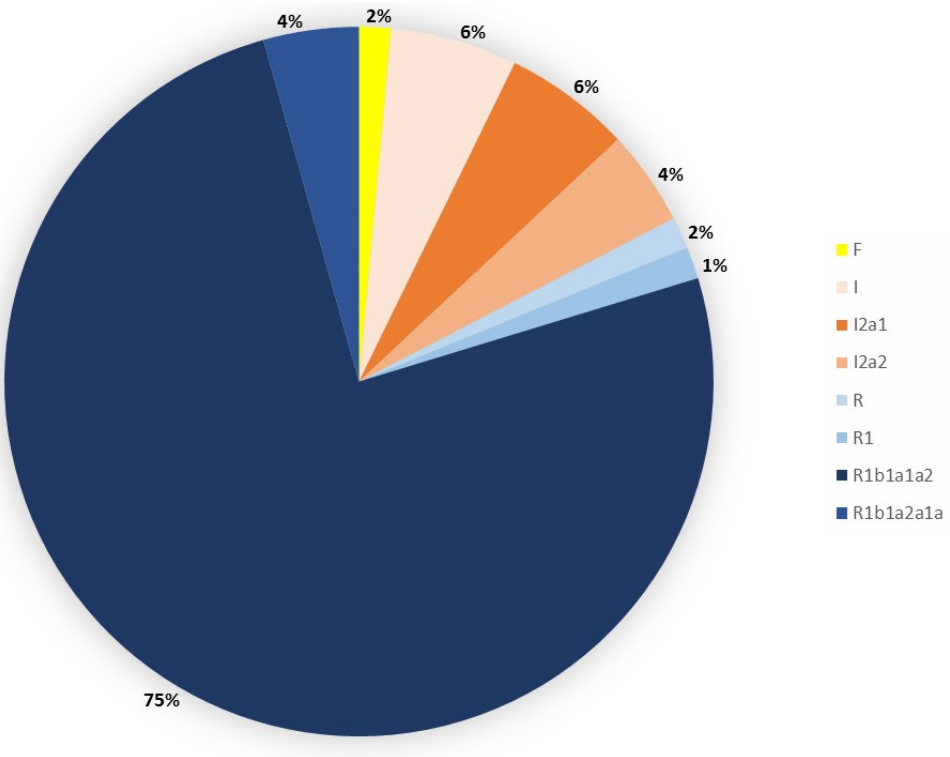

FIGURE 10.10: Y-chromosome haplogroup frequencies of published Bronze Age individuals from the British Isles and those reported in this study.

Overall, only four individuals from the Iron Age in Britain have been identified as male and their Y-chromosome haplogroup has been determined – two published individuals (Schiffels et al., 2016) and three individuals reported in this study, two from the Knowe of Skea (KD004 and KD043), and one from Carsington Pasture Cave (CE004). The two individuals from Hinxton belonged to subclades of R1b1a2a1a (Schiffels et al., 2016), while the two Iron Age individuals from Knowe of Skea and the one from Carsington Pasture Cave all belonged to Y-chromosome haplogroup R1b1a1a2. It is possible that KD004 belonged to a further derived subclade of R1b1a1a2 as one defining SNP each for R1b1a1a2a1a2, R1b1a1a2a1a2c, and R1b1a1a2a1a2c1a2 was also retrieved, and CE004 was typed as R1b1a1a2a1a. In order to not only rely on one single SNP to specify the subhaplogroups, further sequencing is required.

The published Roman and Anglo-Saxon data from Britain only includes two Y-chromosome typed males, who belonged to haplogroups J2 (Martiniano et al., 2016) and I1 (Schiffels et al., 2016), neither of which appears in earlier British samples. Among the 21 Anglo-Saxon and post-Roman males of this study, 18 belonged to subclades of major European Y-chromosome haplogroup R1b1, two belonged to I1a2, and one each belonged to I2a1, I2a2b, and E1b1. The frequencies within R1b1 are shown in Figure 10.11.

The increased frequency of R1b and I2 lineages has been associated with the major expansions of the Late Neolithic and Early Bronze Age across Europe; more specifically, in the case of R1b, to the spread of the Corded Ware culture at the end of the Neolithic, as well as possibly the antecedent Early Bronze Age Yamnaya culture of the Pontic-Caspian Steppe (Silva et al., 2019). Almost all Yamnaya individuals analysed to date fall close to the root of the European R1b1a1a2 cluster, which has been found at high frequencies among the Bronze Age individuals analysed in this study, and also at high frequencies in its subclusters among the analysed post-Roman and Anglo-Saxon samples. This reflects that the impact that the Yamnaya pastoralists and their Corded Ware descendants had on the European gene pool also impacted strongly on the British Isles. Despite being at low frequency in modern-day south-east England, subhaplogroup R1b1a2a1a2c reaches its highest global levels in modern Irish populations ($\sim$80%) and is commonly found in western and northern Britain (Silva et al., 2019).

In the British Neolithic individuals, the observed assimilation of Y-chromosome haplogroup I2 lineages, which are associated with the Mesolithic Atlantic

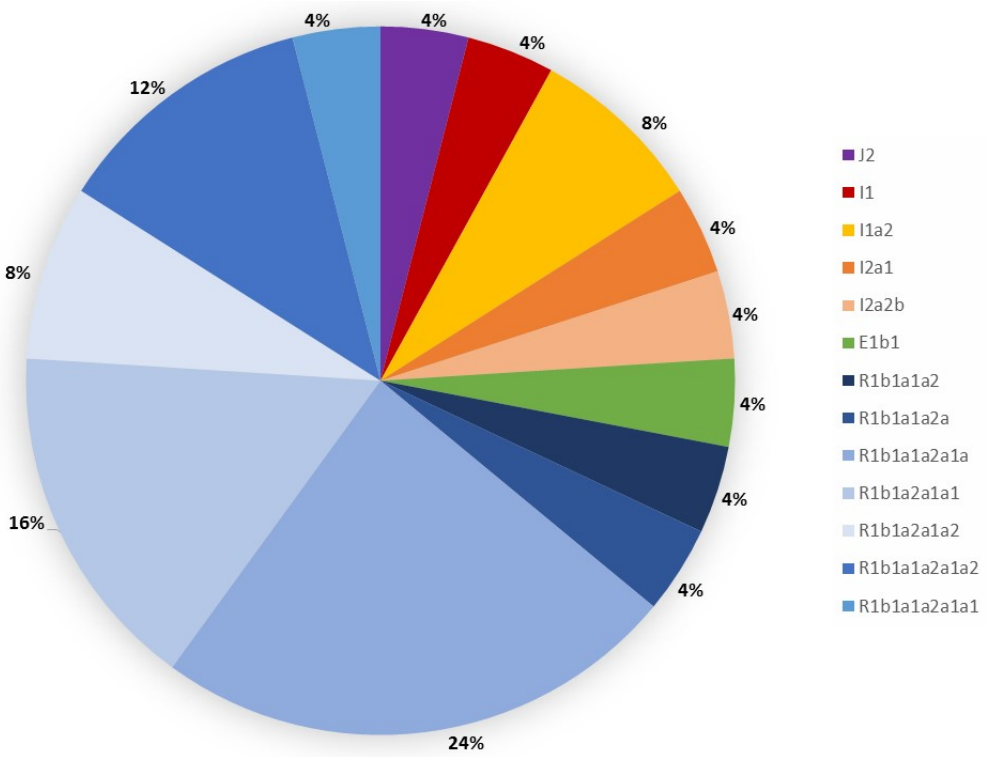

FIGURE 10.11: Y-chromosome haplogroup frequencies of published Anglo-Saxon from the British Isles and (post-)Roman individuals and those reported in this study.

hunter-gatherers, may have taken place (at least in part) during the migration across Europe, rather than once these people arrived into the British Isles (Silva et al., 2019). The levels of hunter-gatherer lineages seen in the Y-chromosome and mitogenomes differ strongly, with 100% assimilation of male lineages but only about a fifth to a quarter of female lineages, suggesting a strong sex bias during the Neolithic migration into north-west Europe (Silva et al., 2019). With the mitochondrial lineages, haplogroup H increased continuously from the Bronze Age until it reached its modern-day frequency during the Anglo-Saxon period. This is very different to the apparent discontinuity seen for Y-chromosome lineages, as R1b almost completely replaced lineages belonging to haplogroup I, and, in the Neolithic specifically, subclusters of I2. Y-chromosome lineages belonging to I1, as well as the R1b-derived cluster R1b1a1a2a1a2, were most likely brought to the British Isles with the Anglo-Saxon migrations, as they have not been seen at earlier dates in the British gene pool (compare Figures 10.9-10.11).

10.4 Sex determination

Osteological and genetic sex determination were not always congruent throughout this study. Where sex had been identified in the ancient human remains, this had either been assumed based on accompanying grave goods (Haak et al., 2008) or osteological analysis. Osteological sex determination is a well established procedure of morphological analysis of ancient human remains, and is widely used in forensic analysis. One of the most reliable skeletal indicators of sex in adults are the pelvic bones (Hrdlička, 1952; Krogman, 1973). Other methods use features of the femur and tibia (Robinson et al., 2011), tooth mineralisation, long bone length, and morphological skull characteristics (Rösing et al., 2007; Chovalopoulou et al., 2013).
Although sex determination of infants and sub-adults has long been considered impossible (Stewart, 1968; Bennett, 1973), refinement of criteria and techniques in the last few decades has supposedly allowed sexing of the infant pelvis using measurements of the ilium (Weaver, 1980). However, a large study comparing several existing methods for sexing, and using new measurements on dimorphic traits of sub-adults, found no effective method to significantly distinguish male and female sub-adult individuals (Satterlee Blake, 2011). Therefore, osteological sex determination, especially of infant and sub-adult remains, still needs further development, and any results have to be considered with caution.
Of the individuals in this study, 36 had an osteological sex identification, 10 of which were uncertain of which two were children. It was not possible to genetically sex one of these individuals but, of the remaining 35, eight were misclassified when compared to genetic sex. Of the 25 individuals with certain morphological sex assignments, 5 were misclassified, which equates to 20%. This leads to the conclusion that, where possible, genetic sex determination should be applied where the aim is to analyse sex biases within sites or even across populations. However, very low coverage genomes might not have enough data to use either karyotyping and/or the Skoglund score (Skoglund et al., 2015) to determine the genetic sex. Based on the dataset analysed in this study, a genome coverage of >0.011x was sufficient to use at least one of the discussed methods for genetic sex determination. In all cases where both the Skoglund script (Skoglund et al., 2013) and the Skoglund score (Skoglund et al., 2015) were applied, the same genetic sex was determined, supporting the robustness of these approaches. When used without

the Skoglund score, the interpretation of karyotype plots of very low coverage samples might be biased towards subjective perception of whether the number of reads of chromosome X are plotting close enough to the regression line to determine an individual as female or not, but it can, in most cases, give an indication where the coverage is too low.

10.5 Conclusions

The use of uniparental markers proved valuable when analysing ancestry of low coverage data. The analysis of the frequencies of maternal and paternal lineages across different time periods from the Neolithic to present-day populations has illuminated the presence of specific haplogroups and refined our understanding of their frequency patterns and their appearance in the British Isles such as, for example, mtDNA lineage H39 in Bronze Age Orkney, mtDNA lineage HV6 in post-Roman Dorset, or Y-chromosome haplogroup outliers such as E1b1.
Genome-wide analysis gave supporting insights into the populations throughout different time periods in the British Isles, as well as an indication of possible North African ancestry in an English Bell Beaker individual (which needs further investigation), as well as African/North African/Near Eastern ancestry in an English post-Roman individual. Kin relationship estimation across cemeteries added an interesting layer to the understanding of social structures during the Bronze Age, Iron Age, and the post-Roman era.
The in-depth analysis of the mitochondrial lineages of an Iron Age woman from the Isle of Skye, and a foetus and a neonate, who had been buried together in what appears to be a sacrificial burial, revealed that intriguingly the female was the mother of only one of the children, which raised questions such as why she was buried with children that were not her own, and why was a possibly pregnant woman apparently killed as a closing ritual to a cave system? In the case of the mutilated young person from Oakridge, genetic data were mainly used to identify the genetic sex, but the fact that the individual turned out to be a young woman opened several questions, such as who was she and why was she punished?
In conclusion, this study has given important insights into the genetic composition of the British Isles, both from ancient and modern data.

Chapter 11

Future work

11.1 Future analysis of modern data

Founder analysis of modern European data is ongoing. This should give an indication of the likely arrival times of mitochondrial lineages into Europe and Britain, which will complement the picture of maternal lineage movements and admixture based on ancient DNA sequencing data. This major founder analysis could also drastically improve our understanding of present day major European mitochondrial haplogroup H, as its dispersal and drastic increase in frequency through time is not yet fully understood.

11.2 Future analysis of ancient data

1. In the recent study investigating a major population replacement in Early Neolithic Britain (Brace et al., 2018), the Outer Hebrides and the Isle of Skye have not been sampled, nor the majority of eastern Scotland. Re-sequencing the samples from Strathglebe, Isle of Skye, to a much higher depth would allow a more in-depth comparison.

2. Further analysis of Bronze Age individuals from Orkney could be of great use to fully understand the extent of population replacement versus continuity on these islands. Although in this study genome-wide analyses support the replacement of populations between the Neolithic and Bronze Age periods, the Y-chromosome and mtDNA lineages also suggest some level of continuity. Future studies would benefit from focusing on islands and remote areas in order to fully understand whether the majority of the Neolithic population of Britain was replaced, or if this was just a phenomenon in distinct geographic areas.

3. The evidence for population continuity from the Bronze Age to Iron Age in Orkney, as shown at the Links of Noltland and the Knowe of

Skea, suggests a very different picture than the postulated major population replacements during the Mesolithic to Neolithic and Neolithic to Bronze Age transitions seen elsewhere in Britain. The generation of more high coverage genomes from across the British Isles during the Bronze to Iron Age transition would allow for a detailed study.

4. The study of genetic continuity versus population admixture during the Iron Age in the British Isles, with a special focus on the Scottish Isles, would certainly be improved by further sequencing to high coverage of the Shetland individual from Milla Skerra.

5. Similarly, more genome-wide data from the Roman, Anglo-Saxon and Viking periods would significantly improve the understanding of population movements and admixture during these times. The study of Worth Matravers presented here already highlights the diversity during the post-Roman period, but, so far, only a few studies have investigated population composition in Roman Britain in any detail. As the Anglo-Saxon cemetery in West Heslerton consists of over 300 burials, a large-scale analysis of this population would be extremely interesting as, not only would it add another layer to our understanding of population genetics during the Anglo-Saxon period, it would also allow for kinship estimation, adding to our understanding of culture and social organisation within burial locations.

6. Generally, the individuals reported here that have high endogenous content should be sequenced to higher coverage, which, as well as allowing a more detailed Y-chromosome analysis of the males, should enable us to investigate selection signals and make more accurate predictions of admixture.

7. The next step in the analysis of ancient populations will be to downscale from analysing entire populations and mass migrations to focus on local groups and investigate their kin relationships. The cemeteries investigated in Bronze Age and Iron Age Orkney, and post-Roman Worth Matravers, as well as the study at Iron Age High Pasture Cave, have already shown that this type of analysis is possible with low coverage data. This type of analysis is adding interesting and important information to our understanding of ancient peoples and their cultures.

Phylogeographic analysis of the British Isles

B.1 Introduction

The geographic distribution of genetic lineages, their phylogeny and their time depth are the basis of phylogeographic analysis. Non-recombining DNA (the mitochondrial genome and the non-recombining region of the Y-chromosome) is widely used to trace genetic lines of descent. The analysis of non-recombining DNA sequences, with the aim of identifying and dating migrations into new geographic areas, is called founder analysis. Founder sequences are used to date lineages that have arisen autochthonously within a specific population or region after immigration from an external source (Richards et al., 2000; Macaulay et al., 2013). This approach uses the variation that occurs in sequences that migrated from the source to the settled population as means of dating them, and being able to distinguish the diversity which has accumulated following the settlement event, from the diversity that existed before, is key to this analysis (Macaulay et al., 2013).
Due to back migration and a generally non-unidirectional flow of migration complicating the identification of founder types, modification of the method and certain assumptions are required. Archaeological information or phylogeographic analysis of the lineages in the two (source and sink) regions of interest is used to assume a migration model. This assumed archaeological model allows for testing the extent of dispersal in each time window within the model (Macaulay et al., 2013). The procedure was formalised by Richards et al. (2000) by developing criteria that take the effects of both gene flow and recurrent mutation into account. These criteria, $f1$ and $f2$, were designed to minimise their effects requiring either one or two derived branches within the source, corresponding to $f1$ and $f2$, respectively (Richards et al., 2000). High-resolution studies can facilitate the identification of founder types that

have moved multiple times (Macaulay et al., 2013). The use of complete mitochondrial sequences for founder analysis, rather than short fragments or SNP capture data, allows for a more nuanced picture, as it accounts for the entire variation of the mitochondrial genome. Therefore, complete mitochondrial genomes were generated to build a large dataset of modern sequences to identify founder types in Britain.

B.2 Materials and Methods

New and published modern whole mtDNA genome sequences were used for the phylogeographic analysis.

B.2.1 New modern samples

For the new sequences sampled as part of this study, consented buccal swabs and/or extracted DNA sent by collaborators, originating from the British Isles and Ireland, France and Germany, were analysed. A subset of 8,359 individuals, provided by BritainsDNA (now incorporated into Source BioScience) in collaboration with Prof. Jim Wilson, was chosen for whole mitogenome sequencing after analysis of frequency patterns. Out of the total dataset, 5,337 were British or Irish. After several months of negotiations, Source BioScience randomly selected 1,618 DNA extracts from the overall available dataset. All available Welsh and Irish samples were sequenced, as well as a randomised number of samples from Scotland and England. The final subset for complete mitogenome sequencing consisted of 677 samples.
A total of 1,381 samples were processed for NGS sequencing of the complete mitochondrial genome. This included modern samples from Britain, Ireland, France and Germany (see Table B.1 for total numbers). 60 Irish and British samples were collected by Dr. Ceiridwen J. Edwards, M. George B. Foody and Peter Harrop. Peter Harrop extracted at the University of Huddersfield under my supervision, while I did the whole genome amplification and further processing. 677 DNA extracts from Britain and Ireland came from Source BioScience, 308 DNA extracts from Germany and 336 DNA extracts from France, were amplified and resulted in a total of 1,381 samples being processed for NGS sequencing of the complete mitochondrial genome. Furthermore, newly sequenced unpublished samples from Belgium (n=16), Greece (n=70), Italy (n=42), Portugal (n=12) and Spain (n=88), were added to the overall batch of sequences for analysis, as well as a total of 3,872 new

sequences from Germany, the Netherlands and Shetland (see Table B.1 for details).

B.2.2 Published data

To facilitate founder analysis all published and online available modern complete mitochondrial genomes were used. Additionally, the whole mitochondrial genome data from Byrne et al. (2018) was used to facilitate the analysis of the generated Irish data, as the sample number of Irish individuals in this study was comparably low. Due to the immense size of the dataset and the shared use of the data for different projects the published data was split into different haplogroups and within the timeframe of this project I generated the phylogenetic trees in xml format for haplogroups H3, H6, H7, H8 and H31. These were combined with all other remaining trees generated by members of the group to run a complete founder analysis on Europe, including the British Isles. Drs. Pedro Soares, Teresa Rito, and Francesca Gandini were involved in the compiling of published sequence data and the generation of phylogenetic trees, as well as Alessandro Fichera, M. George B. Foody, Gonzalo Oteo-Garcia and Marina Silva. Details about the phylogenetic reconstruction can be found in Appendix C.

TABLE B.1: Overview of all new and published samples used in this study.

Country	Sample number	Source	Data type	Collaborators	Published
Belgium	16	DNA extracts	whole-genome sequences	A. Fichera	No
Britain	5,337	Mitotype	SNP data	Source BioScience/Prof. Jim Wilson	No
	677	DNA extracts	whole-genome sequences		No
	60	buccal swabs	whole-genome sequences	Dr. C.J. Edwards, M.G.B. Foody, P. Harrop	No
French	336	DNA extracts	whole-genome sequences		No
Germany	2,881	Sequences	Sequence data	KORA project, Dr. Antonia Flaquer	No
	308	DNA extracts	whole-genome sequences		No
Greece	70	DNA extracts	whole-genome sequences	M.G.B. Foody	No
Ireland	408	Sequences	Sequence data	Byrne et al. (2018)	Yes
Italy	42	DNA extracts	whole-genome sequences	A. Fichera	No
Netherlands	491	Sequences	Sequence data	GONL project, Prof. Walther Parson	No
Portugal	12	DNA extracts	whole-genome sequences	M. Silva	No
Shetland	500	Sequences	Sequence data	Prof. Jim Wilson	No
Spain	88	DNA extracts	whole-genome sequences	G. Oteo-Garcia, M. Silva	No

B.2.3 Modern sample processing

B.2.3.1 DNA extraction of buccal swabs

DNA from buccal swabs was extracted using the PureLink Genomic DNA Kit (ThermoFisher Scientific). The buccal swabs were placed in a sterile 2 ml microcentrifuge tube using tweezers, and the complete cotton swab was pulled off the wooden stick. 400 µl PBS and 20 µl Proteinase K were added to the sample directly, and mixed by pipetting. An equal volume of PureLink Genomic Lysis/Binding Buffer was added to the lysate, and mixed by brief vortexing. After this step the manufacturer's protocol was followed from the incubation step without any further changes. The elution volume was 100 µl and the samples were stored in 1.5 ml centrifuge tubes at -20 °C. The quality of the DNA extracts was assessed by measuring their concentrations using the Qubit 3.0 Fluorometer with the High Sensitivity assay for dsDNA.

B.2.3.2 DNA amplification of complete mitochondrial genomes

The Polymerase Chain Reaction (PCR) was used to increase the targeted DNA fragments in comparison to other genomic DNA in the DNA extract. The set-up for modern samples was undertaken in the modern genetics lab at Huddersfield. To amplify the complete mitochondrial genome (16,568 bp), two fragments were used for each sample. The amplification was set up the same way for both fragments, only changing the primers for each fragment. Nuclease-free water (11 µl), GoTaq®Long PCR Master Mix (PROMEGA) 2X (12.5 µl), 5871for (GCTTCACTCAGCCATTTTACCT) (0.5 µl, 10 pmol), 13829rev (AGTCCTAGGAAAGTGACAGCGA) (0.5 µl, 10 pmol) as primers for the first fragment and 13477for (GCAGGAATACCTTTCCTCACAG) (0.5 µl, 10 pmol) and 6345rev (AGATGGTTAGGTCTACGGAGGC) (0.5 µl, 10 pmol) for the second fragment, and 2 µl of sample DNA. Amplification took place under the following thermal cycling conditions: 2 minutes at 94 °C; 30 cycles at 30 seconds at 94 °C, 30 seconds at 55 °C, 9 minutes at 65 °C, and a final extension of 10 minutes at 72 °C. Amplification products were visually checked to be the correct size using 1% agarose gels running at 80 V for 45 minutes.

B.2.3.3 Purification of PCR products

The PCR products were purified using the Wizard® SV Gel and PCR Clean-Up System (Promega, USA) to remove inhibiting salts and dNTPs, and to concentrate the DNA content. The elution volume used was 50 µl.

B.2.3.4 Measurement of DNA quantity

A measurement of DNA quantity was needed to calculate the necessary volume of each sample, in order to pool the products of the two fragments together equimolarly for high-throughput sequencing. DNA concentration was assessed using 1 µl of the purified PCR product using the Qubit® dsDNA High Sensitivity assay kit on the Qubit® 3.0 Fluorometer. Each sample was measured twice, and the mean value of each sample was used for further calculations in order to minimise pipetting or machine errors.

B.2.3.5 Modern sample preparation for NGS sequencing of mitogenomes

After quantification both fragments were pooled equimolarly with a final volume of 40 µl and a concentration of 1 ng per µl. The pooled samples were then sequenced on a MiSeq250 (PE-Nano x1) by the Earlham Institute (Norwich, UK).

B.2.3.6 Data analysis of modern mitogenome sequences

B.2.3.6.1 Newly sequenced genomes

EAGER (Peltzer et al., 2016) was used for the quality control, removal of duplicates, mapping and SNP calling, using the following settings: AdapterRemoval for the removal of adapters and read merging; bwa-mem to align sequences to the rCRS (Andrews et al., 1999); duplicates were removed using DeDup; HaplotypeCaller was used for SNP calling, with 'Downsampling' set to 250, 'Ploidy' set to 100 and 'Standard Call Confidence' set to 30, and for SNP filtering the 'Minimum Coverage Filter' was set to 2.
In order to filter the mutations and heteroplasmies bcftools v.1.3 was used (Li et al., 2009b; Li, 2011). Mutations with an allele frequency >0.7 were considered variants, whilst mutations with an allele frequency >0.3 and <0.7 were considered heteroplasmies. All heteroplasmies were manually checked in Geneious® (version 6.1.8). Mutations in non-considered positions (around 302-315 including 309.1C(C) and 315.1C, AC insertions and deletions at 515-522, 16182C, 16183C, and 16193.1C(C)) were excluded from analyses. The final haplotypes were used to determine the haplogroup designations with HaploGrep 2 (Weissensteiner et al., 2016) and converted into FASTA files with HaploFasta. Haplogroups of the SNP data of the 5,337 British and Irish individuals from Source BioScience were as well determined using HaploGrep 2 (Weissensteiner et al., 2016).

B.2.3.6.2 Published genomes

Published sequences were aligned to the rCRS using Sequencher™ version 5.1 (`http://www.genecodes.com`), and converted to variants with mtDNAGeneSyn (Pereira et al., 2009). Gaps were cleaned and haplogroup assignment verified with Haplogrep 2 (Weissensteiner et al., 2016).
The 408 mitochondrial genomes published by Byrne et al. (2018) were realigned to the rCRS using bwa aln with -q 15 and -l 1024. Samtools was used to filter, sort and remove duplicates from the alignments (Li et al., 2009b). Alignments were filtered for quality 30 and F4. Variants were called using GATK HaplotypeCaller with a standard call confidence of 30 and sample ploidy 100, in order to identify heteroplasmies (see section B.2.3.6.1). Overall, 349 sequences of the Byrne et al. (2018) dataset passed all quality filters and had accompanying geographical information of the maternal grandmother, and were used for further analysis.

B.2.3.7 Founder Analysis

For the founder analysis a software tool developed in the group of Dr. Pedro Soares, University of Minho, Portugal, was used. To estimate arrival times, founder types were identified and, on the basis of their coalescence times partitioned into clusters that derived from the founder types in the sink population (Soares et al., 2016).
The overall founder analysis of the British Isles, with Britain as a sink population and various mainland European countries as possible source populations, is still ongoing. Results presented in this chapter are founder analyses of haplogroup H3, which is among the most frequent haplotypes of major haplogroup H in Britain, with around 12% of all haplogroup H from Britain being H3.
In order to identify founder types of haplogroup H3 that derived from a source population in central Europe, the following countries were considered to represent central Europe: Austria, Belgium, Czech Republic, Denmark, France, Germany, Luxembourg, the Netherlands and Poland. The total number of samples from these countries in the dataset analysed was 260, whilst the total number of samples in the sink population (the British Isles, *i.e.* England, Scotland, Wales and Ireland) accounted for 108.
For the founder analysis with founder types originating in Iberia, Portugal and Spain (including the Basque country) were considered as the source population. The total number of samples included in the source was 154, and the

samples in the sink were the same as described above.
Founder analyses were carried out including an initial 200 year scan, which is a very fine-scale partitioning of the data, to evaluate arrivals over time more objectively than choosing only archaeological dates. The approach by Saillard et al. (2000) was used to estimate errors in order to allow for non-star-like clustering of founders. The number of samples in the ρ estimation was replaced by an effective number of samples, which was based on the number that would be present in a completely star-like network (Soares et al., 2012). ρ was defined as the average distance in mutations from each sample to the root or most recent common ancestor of the tree/network (Forster et al., 1996). A mutation rate of one mutation every 2,600 years was employed, because the founder analysis software does not use a time-dependent mutation rate, therefore, the average of the time-dependent age estimates was used (Soares, 2009). The calculation of the time-dependent mutation rate accounts for the effect of purifying selection on more recent nodes of the complete human mitochondrial tree (Soares et al., 2009). Different criteria of varying stringency levels for the identification of founder types were employed, *i.e.* $f1$ and $f2$, which are threshold levels minimising the effects of recurrent mutations (Richards et al., 2000), and specifying that matches in the source should have one ($f1$ or two ($f2$) derived branches, but no matches on the tips of the source phylogenies (Soares, 2009). The molecular clock was used to convert the values to time depth as a proxy for minimum arrival times of founder clusters in the sink population (Richards et al., 2000).

B.3 Results

B.3.1 mtDNA SNP data of the British Isles

The mtDNA SNP data of Britain consisted of 2,303 samples from England. The English data included 104 haplogroups, of which 44.90% belonged to 47 subhaplogroups of H and nine subhaplogroups of HV (Figure B.1A). Other diverse haplogroups presented in this dataset were U (eight subhaplogroups; Figure B.2A), haplogroup V (12 subhaplogroups) and haplogroup W (six subhaplogroups). The most frequent (>5.00%) haplogroups among the English samples were: H1 (17.24%), U5 (11.12%), J1 (8.55%), T2 (7.69%) and K1 (7.21%)(Table B.3). For Scotland, 1,926 samples were present in this dataset, including 88 haplogroups. The 43 subclades belonging to haplogroup H

made up around 40.39% of the data (details in Figure B.1B), while other diverse haplogroups were V, U, HV, W and I. The most frequent (>5.00%) subhaplogroups among the Scottish were: H1 (13.24%), J1 (12.98%), U5 (8.10%), K1 (7.48%) and T2 (6.65%)(Table B.3). Within macro-haplogroup U the subhaplogroups with the highest frequency in Scotland were K1 (35%), U5a (24%) and U5b (14%)(Figure B.2). The combined Irish dataset (newly generated sequences n=374, and Byrne et al. (2018) data n=349) consisted of 723 sequences, of which 39.56% belonged to haplogroup H and its subclades (Figure B.1C). Haplogroup U had an overall frequency of 25.45%, with K1 accounting for 8.30%, U5a for 6.22%, U5b for 3.87%, U4 for 2.35%, and K2,U1,U3, U6 and U8 each accounting for less than one percent frequency (Figure B.2C). Haplogroup J had a frequency of 12.03%, with J1 accounting for the majority of it (Figure B.3). The most frequent subhaplogroups in Ireland were H1 with 13.97%, J1 with 11.20%, K1 with 8.30%, T2 with 7.88%, H3 with 7.61 %, and U5a with 6.22% (Table B.3). The Welsh data consisted of 733 samples, including 60 subhaplogroups with 43.93% belonging to 32 subclades of H (details of the subhaplogroups of H are given in Figure B.1). Haplogroups HV, U, V and W were other diverse haplogroups of the Welsh subset. H1 (12.96%), J1 (12.14%), K1 (8.59%), U5 (6.82%), H3 (5.59%) and T2 (5.59%) were the most frequent subhaplogroups (>5.00%) of the Welsh samples (Table B.2). The different contributions of the subhaplogroups of U and JT are given in Figures B.2 and B.3, respectively. An overview of the major haplogroups and their frequency and distribution across the British Isles based on this SNP dataset is given in Table L.1 and Figure L.1 in the Appendix.

Considering the different haplogroup frequencies of the regions within the British Isles, more details appear. The frequency of H1 ranged between 6.13-19.53%, with the minimum in North Wales and the maximum in the Ireland Ulster. Next to haplogroup H1, J1 (0-15.63%) and U5 (4.69-14.29%) were the overall most frequent haplogroups. For more details on the haplogroup frequency and composition per region please refer to Tables L.2-L.3 and Figures B.1-B.3, as well as Figures L.2-L.5 in the appendix. Since haplogroup H had the highest frequency in all countries of the British Isles, the frequencies of its main subhaplogroups was disseminated (Figure B.1). Subhaplogroups H1 and H3 were the most frequent in all four countries ranging from 28-38% frequency and 10-17%, respectively. In England and Wales subhaplogroup H5 reached a frequency of 9% and 8%, respectively, whereas in Ireland and Scotland it had a frequency of 6% and 7%, respectively. In Wales subhaplogroup H6 reached a frequency of 11%, while in Ireland, Scotland and England it

ranged between 4-6% (Figure B.1). The frequency of subhaplogroup H2 differed from 5% in England to 9% in Wales, with 7% and 8% in Scotland and Ireland. H11 was most frequent in Ireland with 4%, its frequency in Scotland and Wales was 3%, while in England it occured with less than 2% and was included in the minor H clades in Figure B.1. The frequency of HV also differed quite strongly between the countries of the British Isles. Its highest frequency was in Ireland with 8%, its frequency in England and Wales was 4% and 3% in Scotland.

TABLE B.2: Haplogroup frequencies per country of the British Isles. Frequencies are given in percent.

FIGURE B.1: Haplogroup H compositions of the Source BioScience SNP data and the Irish sequence data from Byrne et al. (2018) in the four countries of the British Isles. A – England, minor H/HV consists of 32 subhaplogroups with each less than 1%; B – Scotland, minor H/HV consists of 37 subhaplogroups with each less than 1%; C – Ireland, minor H/HV consists of 13 subhaplogroups with less than 0.35%, which is the frequency of H8, HV and HV1; D – Wales, minor H/HV consists of 27 subhaplogroups with each less than 1%.

B.3.2 Phylogeographic analysis of complete mtDNA genomes

A random subset of 677 samples from the British Isles Source BioScience dataset were used for NGS sequencing, along with additional British and Irish samples (60 in total), samples from Germany (308 in total) and France (336 in total). Out of the 1,381 processed samples 106 failed at the sequencing stage or did not pass quality filters, leaving a final dataset of 1,275 sequences (736 British and Irish samples, 328 French and 211 German).

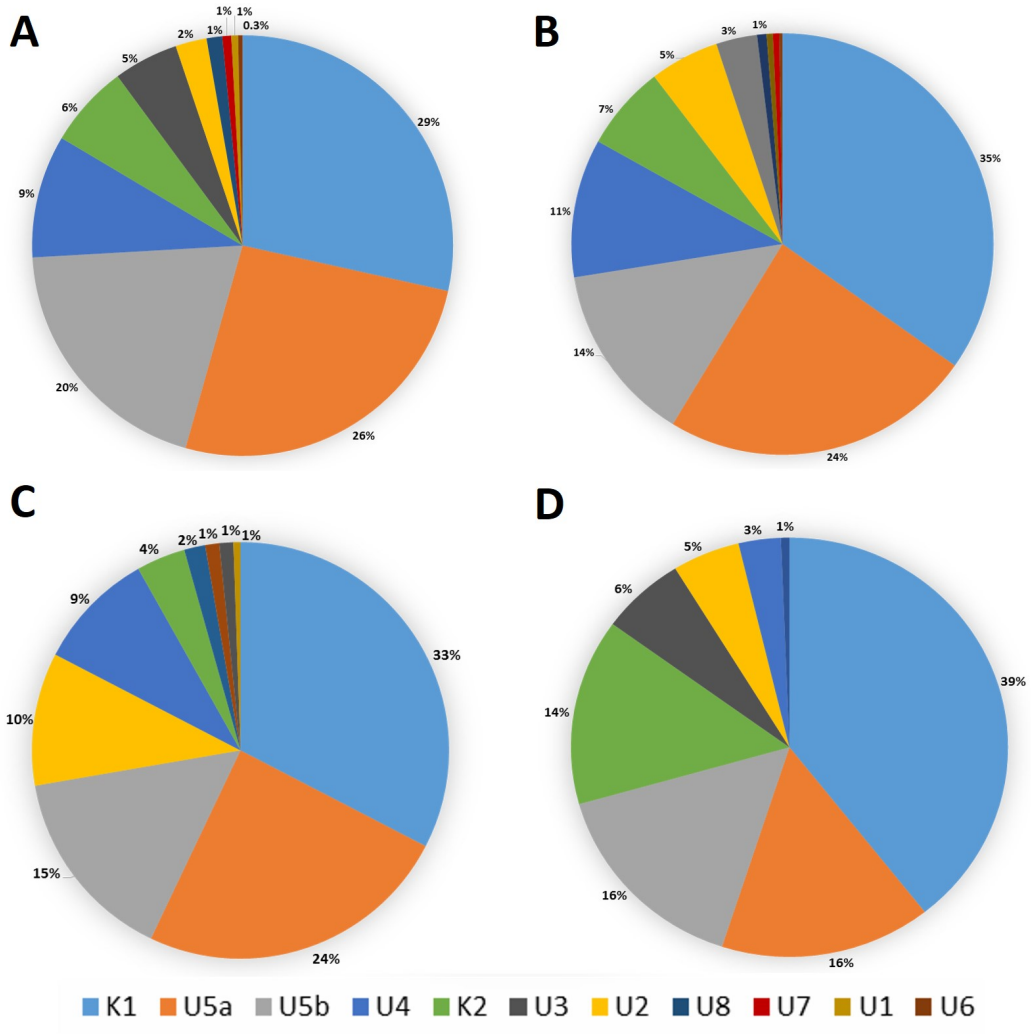

FIGURE B.2: Haplogroup U (including K) composition of the Source BioScience SNP data and the Irish sequence data from Byrne et al. (2018) in the four countries of the British Isles. A – England; B – Scotland; C – Ireland; D – Wales.

B.3.2.1 Haplogroup composition of the British Isles and Ireland

The dataset from the British Isles and Ireland consisted of 736 samples. Of these 192 were from England, 142 from Ireland, 147 from Scotland, 235 from Wales and 20 of unknown geographic origin within the British Isles. As the haplogroup frequencies of the generic samples with unknown geographic origin would not add much detail to the frequency overview, they were excluded from the frequency analysis due to their low number.

In this population dataset, the haplogroups with the highest frequencies were H (36-43%), J (9-20%), U (9-15%), K (7-12%) and T (7-10%). The dataset included 418 different haplotypes, of which 183 belonged to haplogroup H and eight to HV. Other diverse haplogroups were U (with 60 haplotypes),

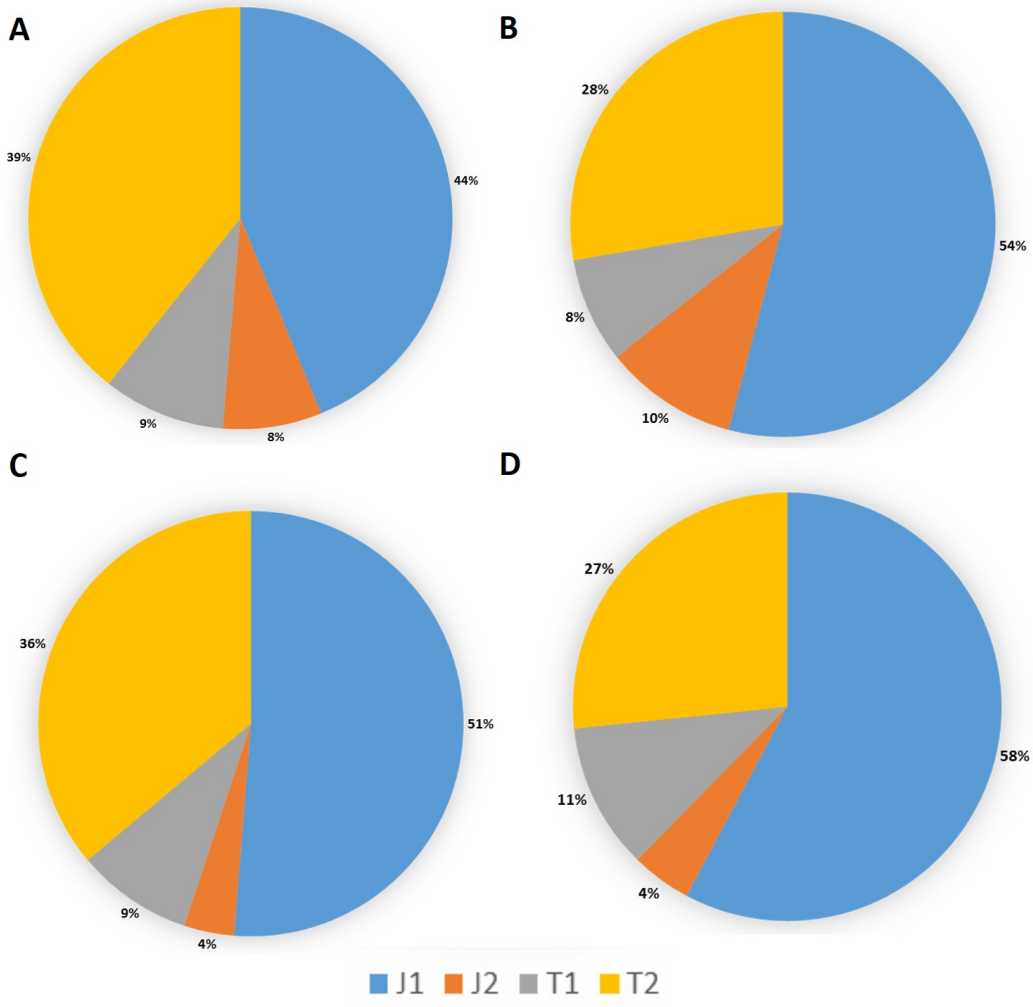

FIGURE B.3: Haplogroup JT composition of the Source BioScience SNP data and the Irish sequence data from Byrne et al. (2018) in the four countries of the British Isles. A – England; B – Scotland; C – Ireland; D – Wales.

K (with 45 haplotypes), J (with 36) and T (with 35)(Table B.4). The most frequent haplotypes among the English samples were: H1 (12.01%), U5 (9.95%), T2 (7.85%), K1 (7.33%), H3 (6.81%), J1 (5.76%), H5 (4.71%). The most frequent haplotypes among the Irish samples were: J1 (19.59%), H1 (14.43%), K1 (7.22%), T2 (6.19%), U5 (6.19%) and H3 (4.12%). The most frequent haplotypes among the Scottish samples were: U5 (10.88%), J1 (10.20%), T2 (7.48%), H1 (6.8%), H3 (5.44%), H2 (4.76%), K1 (4.76%), J2 (4.08%) and X2 (4.08%). Among the Welsh samples the most frequent haplotypes were: J1 (9.36%), H1 (8.94%), K1 (8.09%), H3 (7.66%), U5 (5.11%), T2 (4.68%), H6 (4.26%) and K2 (4.26%).

TABLE B.4: Haplogroup frequencies of the countries within the British Isles based on complete mitochondrial sequences. Frequencies are given in percent. Total percent calculated, excluding the 20 United Kingdom samples with unspecified geographic origin.

Country	mtDNA Haplogroups

B.3.2.2 Haplogroup composition of France

The French data consisted of 328 samples, belonging to 15 different haplogroups. Haplogroups with the highest frequencies were H (44%), U (15%), T (9%), J (8%), and K (8%) (Table B.5). The most diverse haplogroups were H (with 96 haplotypes), U (33), J (22), T (19) and K (17). Amongst these, the most frequent haplotypes were: H1 (15.85%), U5 (9.76%), T2 (8.23%), J1 (7.32%) and H3 (4.88%).

TABLE B.5: Haplogroup frequencies of the French dataset. Frequencies are given in percent.

Country	mtDNA Haplogroup														
	B	H	HV	I	J	K	L	M	N	R0	T	U	V	W	X
France	0.30	44.21	2.44	3.66	7.93	7.62	0.91	0.61	0.61	0.30	9.45	14.63	2.74	2.74	1.83

B.3.2.3 Haplogroup composition of Germany

The German subset consisted of 211 samples, belonging to 13 different haplogroups of which three showed the highest frequencies: H (45%), U (16%) and T (13%) (Table B.6). Most diverse haplogroups were H (with 70 haplotypes), U (28), T (14), J (13) and K (10). The most frequent haplotypes in this subset were H (16.11%), T2 (10.43%), U5 (8.53%), J1 (8.53%) and H5 (5.21%).

TABLE B.6: Haplogroup frequencies of the German dataset. Frequencies are given in percent.

Country	mtDNA Haplogroups												
	C	D	H	HV	I	J	K	N	T	U	V	W	X
Germany	0.47	0.47	45.50	1.90	2.37	9.48	5.69	0.47	12.80	15.64	1.42	2.84	0.95

B.3.3 Founder Analysis

Founder analyses were carried out with complete mitochondrial genomes to investigate the genetic input of haplogroup H3 into Britain through time.

B.3.3.1 Central Europe to Britain

The 200-year scan of founder-lineages dispersing into Britain identified two major coalescence peaks under the two employed criteria, $f1$ and $f2$, at 4 kya and 7.0-7.2 kya (Figure B.4).

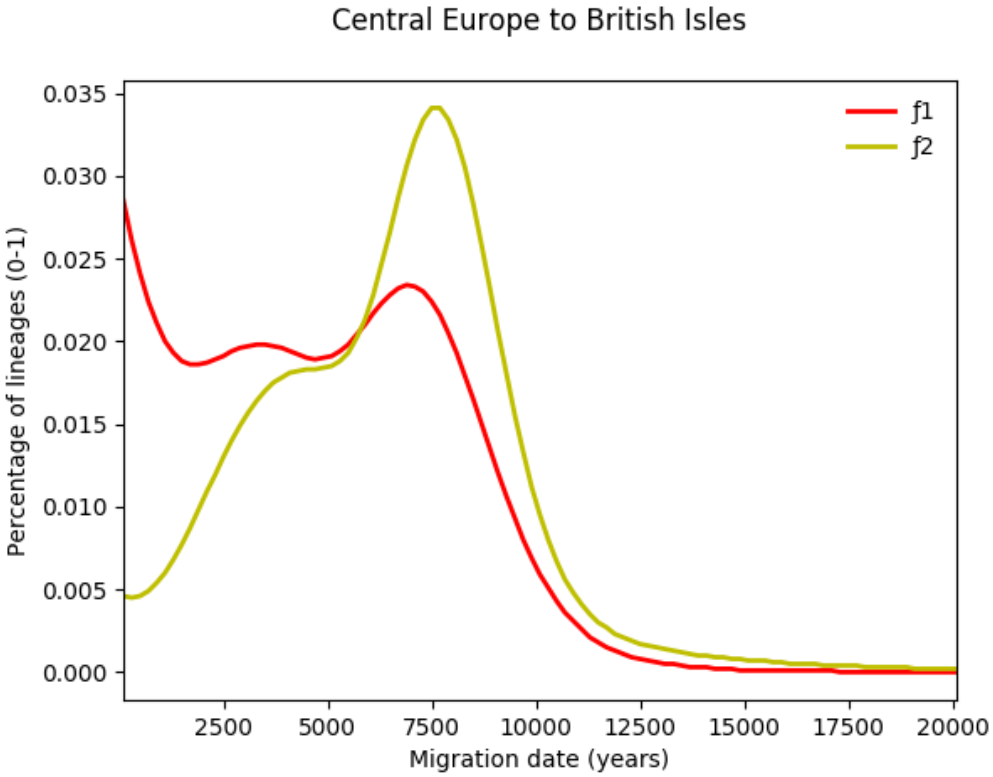

FIGURE B.4: Founder analysis results for Britain, assuming Central Europe as source for mtDNA variation. Probabilistic distribution of mtDNA founder clusters across migration times scanned at 200-year intervals from 0-20 kya, using two criteria for founder identification, $f1$ and $f2$.

The founder types in Britain were then partitioned using a migration model informed not only by the results of the scan, but also archaeological evidence, to quantify the contribution of the immigration events to the extant mtDNA gene pool in Britain. The model using Central Europe as source assumed migrations at 4 kya and 7.1 kya, corresponding to Neolithic/Bronze Age and pre-Neolithic migrations (Figure B.5). An additional dispersal at 0.1 kya was assumed to be due to historical/recent gene flow.

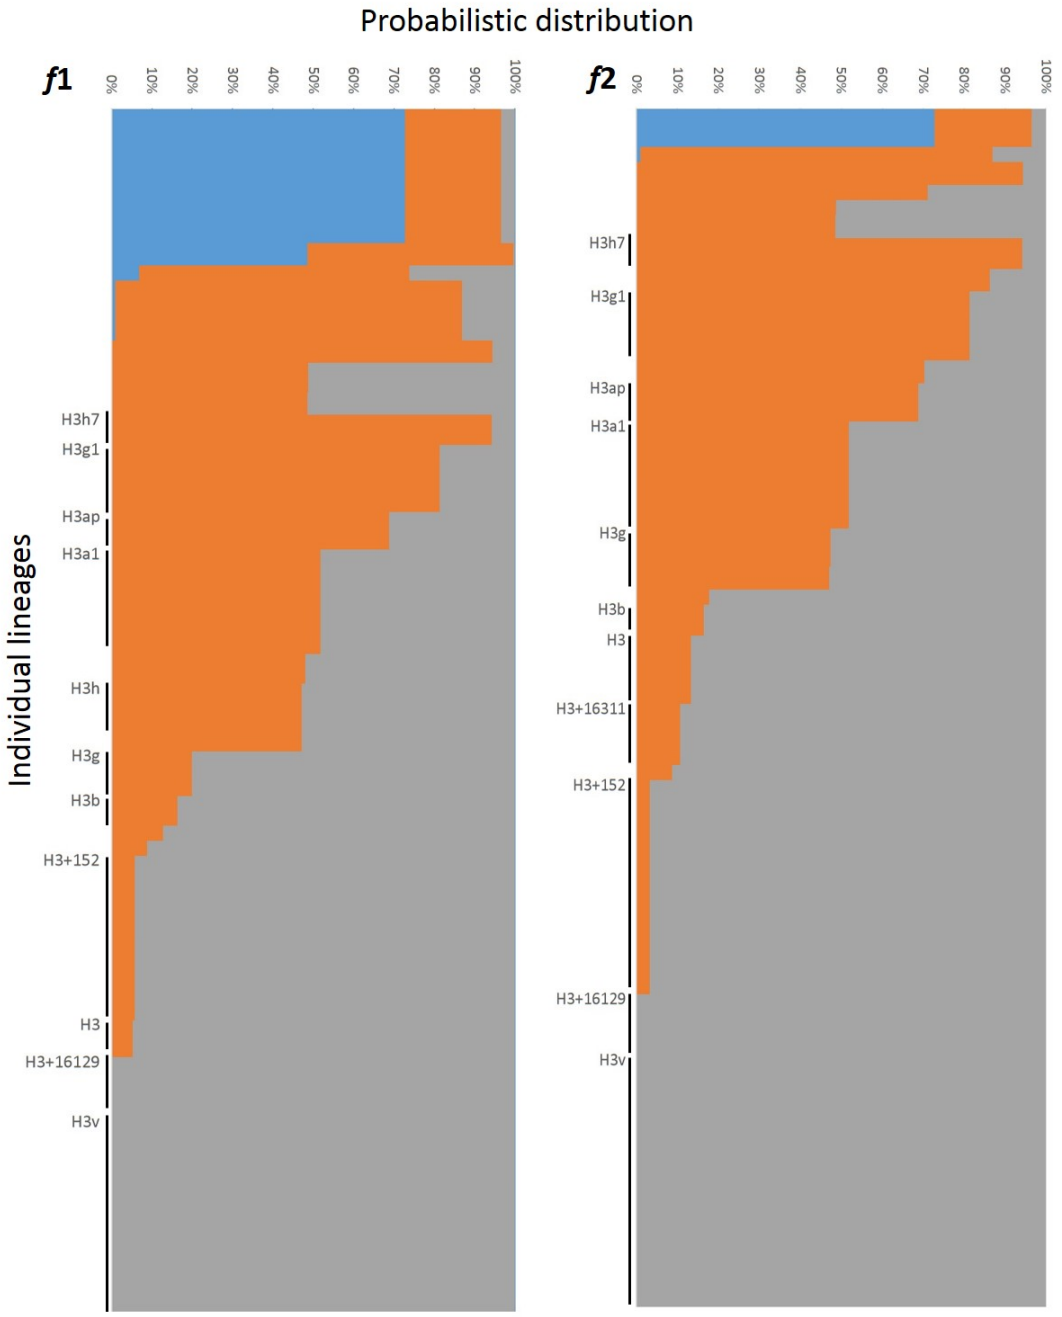

FIGURE B.5: Probabilistic distribution of each individual lineage in mtDNA variation in a three-migration model using two criteria, $f1$ and $f2$, for founder identification. Individual founder clusters with more than 2% frequency in overall Britain (sink population) are indicated at the left-hand side of each plot. Blue = migration at 0.1 kya; Orange = migration at 4 kya; Grey = migration at 7.1 kya.

B.3.3.2 Iberia to Britain

The 200-year scan of founder-lineages dispersing into Britain identified two major coalescence peaks under the two employed criteria, $f1$ and $f2$, at 3.8-4.1 kya and 7.0-7.2 kya (Figure B.6).

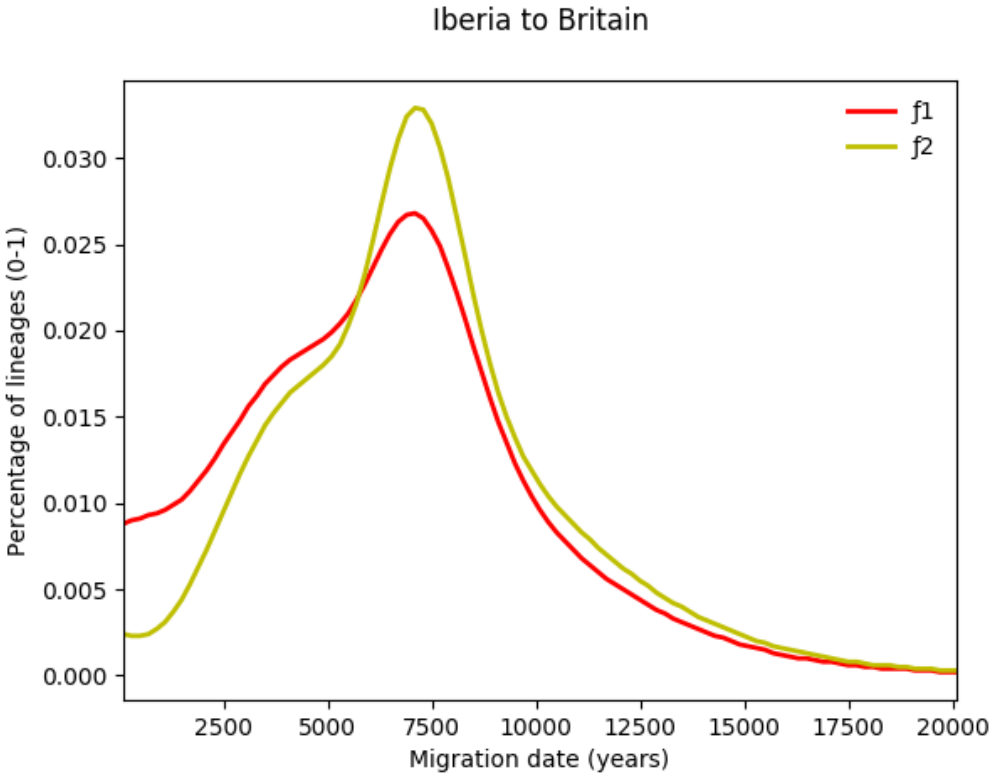

FIGURE B.6: Founder analysis results for Britain, assuming Iberia as source for mtDNA variation. Probabilistic distribution of mtDNA founder clusters across migration times scanned at 200-year intervals from 0-20 kya, using two criteria for founder identification, $f1$ and $f2$.

As before for central Europe, the founder types in Britain were partitioned using a migration model informed by archaeological evidence. The model using Iberia as the source assumed migrations at 4 kya and 7.1 kya, corresponding to Neolithic/Bronze Age and pre-Neolithic immigrations. An additional dispersal at 0.1 kya was assumed to account for any historical/recent gene flow (Figure B.7).

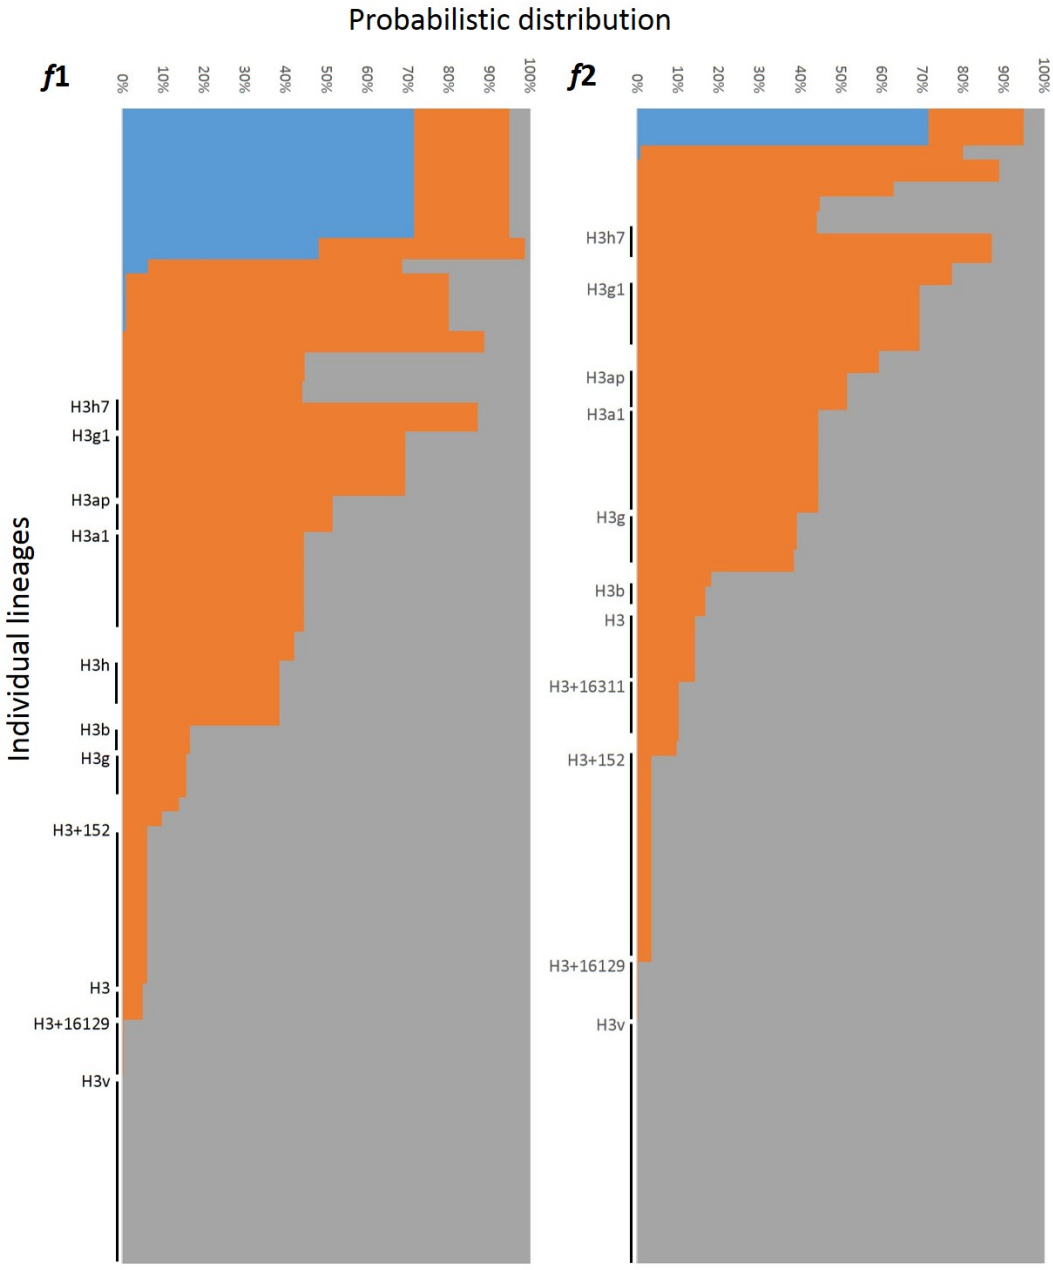

FIGURE B.7: Probabilistic distribution of each individual lineage in mtDNA variation in a three-migration model using two criteria, $f1$ and $f2$, for founder identification. Individual founder clusters with more than 2% frequency in overall Britain (sink population) are indicated at the left-hand side of each plot. Blue = migration at 0.1 kya; Orange = migration at 4 kya; Grey = migration at 7.1 kya.

B.4 Discussion

The haplogroup composition of H differs only slightly among the four countries in the modern SNP data of the British Isles (Figure B.1). H1 varied between 38% in England and 28% in Wales, while it comprised about 30% both in Scotland and Ireland. The largest percentage of H3 was found in Ireland. The higher frequency of H3 in Ireland compared to the rest of the British Isles might be due to its likely origin in Iberia and its northward spread along the Atlantic fringe. As discussed to some extent in Appendix C mtDNA haplogroup H3 has its frequency peak in Iberia and was found in Neolithic Portugal (Olalde et al., 2018).
Haplogroups H*, H1-H7 and HV were the majority haplogroups in all countries, whereas haplogroup H11 was absent in England, but contributed with 3-4% to the genetic landscape of Scotland, Ireland and Wales. Haplogroup H11 is mainly found in modern Denmark (21%), Britain and Ireland (95%) and Finland (8.2%), and has so far been found in Neolithic Lithuania (Mittnik et al., 2018), Early Bronze Age Germany (Brotherton et al., 2013), and Middle Bronze Age Hungary (Allentoft et al., 2015).
The country with the most subgroups contributing to the majority of the data was Scotland. Two of the haplogroups, H8 and H13 respectively, were present to an obviously larger degree in the Scottish population than in the other populations of the British Isles. Haplogroup H13 has been associated with the Yamnaya culture of the Caucasus (Haak et al., 2015).
North and South Wales (NW and SW respectively) differed in several aspects from each other (for an overview, see Figure L.5). The frequency of H1 differed about 10% between NW (6.1%) and SW (16.2%). The frequency of H3 was slightly higher in the North, but the frequencies did not differ significantly. Most of the minor H subhaplogroups were virtually absent in NW, but present in low frequencies in SW. J1 had its highest frequency in NW, with 20.3%, but was much lower in SW with 8.6%. Also the frequency of haplogroup V differed greatly between the North and South of Wales, with 7.1% and 1.4% respectively (Table B.3). Comparing the distribution of the most common haplogroups across the British Isles, it was obvious that H1 was the overall most frequent haplogroup. The average haplogroup frequency of H3 was slightly higher in England and Ireland than in Scotland and Wales, as were the average frequencies for HV, I3, I4 and X2. Instead, the average frequency of haplogroup H8 was higher in Scotland and Wales than in England, while it was absent in Ireland. A similar pattern was observable for

haplogroups I1, I2, J1, T2 and U5, except they also appeared in Ireland (Tables B.2 and B.3).

The comparison of the haplogroup frequencies of the SNP data with the haplogroup frequencies of the complete mitogenome data, showed that the overall frequency patterns do not differ very much. Haplogroups H (40.7%), J (13.8%), U (12.7%), K (9.1%), and T (8.2%) were the most frequent haplogroups, differing only slightly in the frequencies of the two datasets. The biggest differences were frequencies within Ireland, as H only accounted for ∼36% and J for ∼20%, rather than ∼40% and ∼11%, respectively.

Founder analysis was carried out to investigate the genetic input into Britain through time, with complete mitochondrial genomes. The 200-year scan of founder lineages dispersing into Britain identified two major coalescence peaks under the two employed criteria, *f1* and *f2*, for both assumed source populations, Central Europe (Figure B.4) and Iberia (Figure B.6), at 4 kya and 7.1 kya, and 4 kya and 7.1 kya, respectively. The coalescing at the time of the first settlements (∼8 kya) accounted for ∼43 to 59% of modern H3 lineages in Britain, assuming a central European source, and ∼46 to 59% assuming Iberia as the source (Figures B.5 and B.7).

Using central Europe as source, the oldest arrivals date to ∼8 kya, largely lineages basal to H3, lineages of H3v, H3+16129, and H3+152. The lineages with the biggest impact during the Neolithic/Bronze Age migrations were H3h7 and H3g1, as well as some minor clades with less than 2% frequency in the sink population, such as for example minor H3v subclades, H3b1b, H3y, H3aa, and H3z+152.

Using Iberia as source population, the oldest arrivals date to ∼7 kya, largely lineages basal to H3, H3v, H3+152, and H3+16129. Lineages with the biggest impact during the Neolithic/Bronze Age migrations were H3h7 and H3g1, as well as some minor subclades with less than 2% frequency in the sink population, such as for example minor lineages of H3v and H3z+152.

Generally, no major differences can be seen between the *f1* and *f2* criteria in both analyses. The likely overestimation of recent migrations of the *f1* criterion are expected, due to it being less conservative, as it allows only one derived branch.

When matching the identified founder types of haplogroup H3, with the biggest proportion of genetic input into Britain, to known ancient samples from the sink and source populations, only a few individuals carrying those haplogroups were found. The oldest individual belonging to basal H3 dates

to the Early Neolithic in Portugal (Olalde et al., 2018), other individuals belonging to this haplogroup were found in France and Scotland, however, this haplogroup was still most prevalent in Iberia during the Middle Neolithic. The presence of individuals along the western/northwestern extent of Europe, namely the Atlantic fringe, belonging to this lineage suggest a spread with the Atlantic Neolithic, across and into central Europe, supported by the finds from Germany (Brotherton et al., 2013). By the Bronze Age H3 spread west along the Mediterranean to Sardinia and into northeastern Europe (Brotherton et al., 2013; Günther et al., 2015; Mathieson et al., 2015; Olalde et al., 2015; Lipson et al., 2017; Olivieri et al., 2017; Olalde et al., 2018). To date the Scottish Neolithic sample belonging to basal H3, is the only ancient sample found to belong to one of the identified founder types. The founder analysis using central Europe as source differs quite significantly from published data. The source population for the Neolithic arrivals to Britain was mostly Iberia, while central European lineages mainly arrived with the Bell Beaker migrations into Britain (Olalde et al., 2018). The discrepancy between the here presented results and the published data is possibly due to low sample sizes in the source populations of central Europe (n=244) and the sink population of the British Isles (n=108). Founder analysis with a larger dataset would hopefully resolve this issue.

Appendix C

The European haplogroup H enigma

C.1 Introduction

During the Last Glacial Maximum (LGM), the majority of European populations either became extinct or retreated to southern refugia, and so a large fraction of the surviving lineages today derive from a founder effect or bottleneck associated with this event (Richards et al., 2000). Most European mitochondrial haplogroups have a Near Eastern origin and arrived in the continent during the Palaeolithic, or with the Neolithic transition and migrations from eastern populations (Torroni et al., 1998; Achilli et al., 2004; Sampietro et al., 2007; Brandt et al., 2013), and, for many haplogroups, multiple arrivals into Europe at different time periods are very likely (Achilli et al., 2004; Brotherton et al., 2013).

Among modern mitogenomes, a peculiar observation is the dominance of haplogroup H in present-day Europeans. The complex evolutionary history of this haplogroup makes it uncertain when and how it became the dominant European haplogroup. H is thought to have evolved in the Near East and Caucasus region and reached Europe during the Palaeolithic, although a considerable increase in frequency occurred during the Neolithic period (Achilli et al., 2004; Soares et al., 2010; Brotherton et al., 2013). Therefore, the evolution of H is still questionable. Haplogroup H has been argued to have originated in the Near East between 35,000 and 25,000 years ago (Torroni et al., 1998; Álvarez-Iglesias et al., 2009), which is a much older age estimate than the $\sim$18 kya reported by Soares et al. (2010). It clusters within the branch of macro-haplogroup R0, which is primarily Eurasian, with H contributing between 40 and 60% of all European haplogroups seen today (Achilli et al., 2004; Roostalu et al., 2007; Brotherton et al., 2013).

H has a seemingly uniform spread across Europeans, but it contains a complex substructure of phylogeographically informative subclades (Loogväli et al., 2004). It has an extreme star-like phylogeny, with the vast majority of subclades directly branching from the root, and a great majority of the branches indicated by only one defining mutation. The most common and widespread subhaplogroups are H1, H2 and H3, but H4 to H19 are also rather common. Conversely, the majority of the 102 remaining named subclades are minor, represented by only a few individuals. Within Britain the frequencies of most common subhaplogroups are different to the most common subhaplogroups within Europe, e.g. H5 has a higher frequency than H2, and H10 and H12 are very rare. The unique structure and distribution of H, and the peculiar frequency patterns of its subclades, has been widely discussed (Richards et al., 2000; Achilli et al., 2004; Loogväli et al., 2004; Roostalu et al., 2007; Torroni et al., 2006; Brotherton et al., 2013). The diversity seen in H is distinctive and makes it difficult to understand the origin of the different clades. The dominating star-like structure of H and its major subhaplogroups H1 and H3 have been thought to suggest dramatic late-glacial expansions (Torroni et al., 2006).

In Mesolithic hunter-gatherers from Central and Northern Europe, haplogroup H is virtually absent. This suggests that H was introduced from the Near East and Southeast Europe before the Linearbandkeramik (LBK) period, as H is seen after this time with an increasing frequency (Brotherton et al., 2013). In contrast, short fragment sequencing information suggested that haplogroup H was already present during the Mesolithic in the Iberian peninsula (Hervella et al., 2012). Complete genome sequences of ancient samples from the pre-Neolithic in Iberia could so far not support this.

Most of the subclades seen in the present-day Near East and Caucasus expanded into Europe after the LGM, but probably before the Holocene (Roostalu et al., 2007) and, during the Neolithic, there was a consistent and strong exponential growth, especially in Iberia from where it spread into Central and Northwestern Europe (Achilli et al., 2004; Brotherton et al., 2013). Neolithic processes, such as demographic changes during the Middle Neolithic period and the Bell Beaker phenomenon during the Bronze Age, are likely key factors for the massive expansion and increase of haplogroup H in Western Europe (Brotherton et al., 2013; Brandt et al., 2015). The subhaplogroup diversity of H that was established during the Middle Neolithic can still be observed in the present-day populations of Central Europe (Brotherton et al., 2013). The "Atlantic zone" expansion that followed the LGM, 15,000-10,000

years ago, might have carried H lineages into Central and Northern Europe (Torroni et al., 1998; Brotherton et al., 2013). This also supports the hypothesis that one of the earliest populations of the British Isles, which would have included haplogroup H, may have spread up the Atlantic littoral, with sailors reaching Ireland and Wales before spreading into Central Europe (Cunliffe, 2013).

The classification of haplogroup H lineages by first hypervariable segment (HVS-I) is hindered by mutations at fast-evolving nucleotide sites that frequently occur. Additionally, sequence information of just the HVS region leaves a substantial fraction of the haplogroup H phylogeny unresolved. The analysis of haplogroup H diversity and the phylogeography of European maternal lineages thus depends upon full mitochondrial genome information from representative population samples and geographic distribution (Loogväli et al., 2004). The analysis of distinct subhaplogroups of H should reveal spatial frequency patterns and migration events (Achilli et al., 2004), such as the origin and spread of haplogroup H3, which is associated with the spread of the Neolithic and the Bell Beaker culture from Iberia into Central and Northern Europe (Álvarez-Iglesias et al., 2009). Furthermore, haplogroup H7 has no HVS motif and has hitherto been completely invisible in previous studies not using complete mitochondrial genomes.

In the chapter, subhaplogroups H3, H6, H7, H8 and H31 have been analysed in parallel for their spatial frequency patterns. H3, along with H1, are the most common subclades in Western Europe, with the highest frequencies seen in Iberia. Between them, they are the most common subhaplogroups within H in Europe (Brotherton et al., 2013). They are found in similar geographic areas, but H3 represents a much smaller fraction of H than H1 (Achilli et al., 2004). Subhaplogroups H3, H6 and H8 show distinct phylogeographic patterns (Loogväli et al., 2004). Together with H7, H3 and H6 cover the majority of Finnish, US/UK and Galician haplogroup H sequences (Herrnstadt et al., 2002; Loogväli et al., 2004; Quintáns et al., 2004). The overall frequency of these three haplogroups in Britain is 9.14% (Dulias, 2019). Furthermore, H6 shares a state at position 16362 with the clade of H8 (Loogväli et al., 2004) and H31, while the clade of H8 and H31 is defined by a mutation at position 146. Therefore, subhaplogroups H3, H6, H7, H8 and H31 have been analysed in parallel for their spatial frequency patterns in this chapter.

C.2 Materials and Methods

C.2.1 Materials

Along with newly generated data, all available published data of complete modern and ancient mitochondrial genomes was used to reconstruct phylogenetic trees of haplogroups H3, H6, H7, H8 and H31. Samples with unknown geographic origin, as well as unspecified "European" samples and those from outside Europe that have European/Caucasian ancestry (e.g. USA), were included in the phylogenetic analysis, as more samples allow for a more precise phylogenetic tree reconstruction. These were removed from the detailed phylogeographic analysis, as they do not contribute any geographic information.

C.2.2 Phylogenetic analysis

Most commonly, discrete-character methods, such as parsimony and maximum likelihood, are employed to infer evolutionary trees (Salemi et al., 2009). These approachs are based on the concept of using the minimum number of mutations to account for the branching within the tree. The phylogenies of complete European mitochondrial lineages were reconstructed using mtPhyl V4.015 (Eltsov et al., 2011) (`https://sites.google.com/site/mtphyl/home`), applying the discrete-character method maximum parsimony. Recurrent mutations can cause mtPhyl to provide a putative tree, which might differ considerably from the most parsimonious tree, especially when dealing with a large dataset. Therefore, all phylogenetic trees reconstructed with mtPhyl were manually reviewed based on mtDNA PhyloTree build 17 (`http://www.phylotree.org/tree/index.htm`). Heteroplasmies and "hotspot" mutations were not considered for the phylogenetic trees (see subsection B.2.3.6, exceptions are position 152 and position 16311), and the molecular clock developed by Soares et al. (2009) was used for the mutation rate. The reviewed parsimonious phylogenetic trees were then converted into xml trees as input files for Founder Analysis used in Chapter B.

C.2.3 Phylogenetic age estimation

The phylogenetic framework assumes that the evolution of observed sequences follows a tree structure (Salemi et al., 2009). Maximum likelihood infers the probability of point mutations along a branch of a phylogenetic tree, thereby

determining the tree topology, branch lengths and parameters of the evolutionary model (Salemi et al., 2009). The average number of mutations between a cluster of sequences and their most recent common ancestor within a parsimonious phylogenetic reconstruction can be calculated as a rho statistic (ρ) (Forster et al., 1996). Originally, this formula assumed that all mutations were independent, which is a very rare occurrence, and therefore the formula was revised to take both the tree shape and the type of counted mutations into account for the variance calculation (Saillard et al., 2000). Rho (ρ) and sigma (σ^2) were obtained from the coalescent time estimates exported from the Founder Analysis software, which furthermore outputs the age estimates using Soares' clock, which accounts for purifying selection (Soares et al., 2009).

C.3 Results and Discussion

Haplogroup H has been proposed to have originated in the Near East ∼18 kya (Soares et al., 2010), and then expanded with a Paleolithic wave into Europe and was further involved in the repopulation of Central and Northern Europe from ice-age refugia after the LGM (Achilli et al., 2004). As the complete molecular dissection of subhaplogroups of haplogroup H and their spatial distribution and founding events is still under analysis, only the subhaplogroups that I analysed (H3, H6, H7, H8 and H31)are presented here.

C.3.1 Phylogeny of H3

For the phylogenetic reconstruction of mitochondrial haplogroup H3, 1,292 published and unpublished sequences were used. The references and numbers of published sequences are given in Table C.1. 29 published ancient sequences were also included in the analysis, and these derived from the Czech Republic (n=2), Denmark (n=2), France (n=1), Germany (n=9), Portugal (n=1), Russia (n=2), Scotland (n=3), Spain (n=10) and Switzerland (n=1) (Brotherton et al., 2013; Allentoft et al., 2015; Günther et al., 2015; Haak et al., 2015; Mathieson et al., 2015; Lipson et al., 2017; Olalde et al., 2018). 275 newly generated sequences were included; 92 from Germany, 65 from Spain, 57 from the British Isles and Ireland, 23 from Italy, 16 from the Netherlands, 14 from France, six from Belgium, one from Cyprus and one from Luxembourg.

H3 is one of the major subclades of haplogroup H, and is widespread and common among Europeans. Similarly to haplogroup H as a whole, H3 also has a star-like phylogeny, although with fewer nested clades. In general, most subclades of H3 are defined by one single mutation and branch directly from the root, which is similar to the overall structure of haplogroup H. H3 accounts for up to 18% of haplogroup H. It has a ρ age estimate of $\sim$9.4 thousand years ago (kya), which corresponds to the late Mesolithic/Early Neolithic (Table C.2). It is defined by position 6776 and is divided into five major and several minor subclades. The major subclades are H3b ($\sim$9.5 kya) accounting for $\sim$6% of H3, H3c (9 kya) accounting for $\sim$5%, a 99% Sardinian clade defined by position 93 (6.6 kya) accounting for $\sim$17%, a clade defined by position 16311 (7.6 kya) accounting for $\sim$8%, and a cluster defined by position 152 ($\sim$8.2 kya) accounting for $\sim$20% of H3 that includes the rather small branch of H3a ($\sim$8.3 kya). The age estimates (ρ) of the different branches within H3 are controversial; for example, H3b is older than H3, but this is

due to the very large confidence intervals around the dates. The ρ estimate of the Sardinian specific clade that accounts for ∼17% of the reconstructed H3 in this analysis also is problematic, as its estimated age is much younger compared to the Sardinian specific subclades of H3 reported in Olivieri et al. (2017), although the confidence interval covers the reported age of 9-10.5 kya. These highlight that ρ calculations are rather imprecise compared to maximum likelihood (ML) age estimates. Calculating ML age estimates would support the discussion and give more precise dates of the branches.

>>> H3av	0.571	0.286	1472	29 - 2929

Less than 1% of the samples within H3 are from outside Europe (including geographically European parts of Russia). Those samples are from the Caucasus, India, Iran, Tunisia and Japan. Modern samples at the root of H3 are found mainly in Italy (including Sardinia), Spain (including the Basque country), plus single instances in Denmark and England. Fifteen of the 29 ancient H3 sequences are basal to H3; Late Neolithic Germany and France (n=3) (Brotherton et al., 2013; Haak et al., 2015; Olalde et al., 2018), Neolithic Portugal and Scotland (n=2) (Olalde et al., 2015; Olalde et al., 2018), Early Bronze Age Germany (n=1) (Brotherton et al., 2013), and Chalcolithic Spain and Czech Republic (n=9) (Günther et al., 2015; Mathieson et al., 2015; Lipson et al., 2017; Olalde et al., 2018). This fits largely with the argument of Iberia being the source of H3 (Achilli et al., 2004; Torroni et al., 2006; Roostalu et al., 2007; Soares et al., 2010), as H3, together with H1, has a frequency peak in Iberia. The Franco-Cantabrian refugal area in Iberia appears to be the source of late-glacial expansions of hunter-gatherers who repopulated Central and Northern Europe after the LGM (Achilli et al., 2004). However, recent ancient DNA analysis of sequences from Iberia showed that most of Iberian mitochondrial haplogroups in that period were U5b (Sánchez-Quinto et al., 2012). Based on the sequences found at the root of H3, an Iberian origin is a possibility, but an origin in Italy cannot be excluded. The high frequency of H3 in Sardinia and the presence of several Sardinian specific lineages within H3

(Olivieri et al., 2017), as well as the large Sardinian cluster seen in this analysis and the presence of basal H3 sequences originating in Sardinia, all support Sardinia as a putative origin of haplogroup H3. Recent ancient DNA analyses of Bronze Age Iberia reported several basal H3 sequences from Chalcolithic Iberia (Günther et al., 2015; Mathieson et al., 2015; Lipson et al., 2017; Olalde et al., 2018), but one individual from the Nuragic period (3008 ± 25, MAMS-26895) in Sardinia has been reported as basal H3 (Olivieri et al., 2017).

Haplogroup H3 is more frequent in the West (80% of samples) than the East (remaining 20%) of Europe and almost absent in the Near East and Anatolia as already reported (Loogväli et al. (2004)) and as described above. Olivieri et al. (2017) suggested that haplogroup H3 may have arrived prior to the Neolithic in Sardinia, either from Spain or elsewhere in the Western Mediterranean. In order to identify the likely source population of H3, Founder Analysis was undertaken as described in chapter B. The analysis is currently on-going and only preliminary results are presented in chapter B with a focus on the British Isles. The overall analysis of haplogroup H is very complex and does not fit within the major aim of this thesis.

H3a, H3g, H3i, H3j and H3k all cluster within the branch defined by position 152. Two modern German samples are basal to 152, as well as one Middle Neolithic German sample from Salzmünde and one sample from the Unetice culture in Germany (Brotherton et al., 2013). This suggests that H3 already arrived in Central Europe by the time of the Middle Neolithic ($\sim$6 kya). Within H3a (8.3 kya), all samples cluster inside H3a1 (5.7 kya), which has a basal Danish sample and is 25% Scottish, with a further 14% from Ireland and Britain, H3a1a is exclusively British. It is otherwise found in Italy, the Netherlands and Poland. This distribution and the origin of the basal samples supports a spread of H3a from Germany or Central Europe mainly towards the Northwest and, with lower frequencies, towards the South and East.

H3g is the biggest clade of this branch. It has an age estimate of 7.5 kya, two Late Bronze Age Srubnaya samples from Russia(Mathieson et al., 2015) at the base, as well as a sample from Armenia and two samples from Denmark. The Srubnaya culture has been associated with Indo-Aryan dispersals from Central Asia into South Asia (India) and West Eurasia (Silva et al., 2017). The modern Indian sample which is basal to H3g is potentially a direct connection to the Srubnaya dispersals into South Asia. H3g1 (3.6 kya) has six basal Danish samples and is overall $\sim$36% Danish. H3g1b (1.5 kya) is entirely British (mainly found in Scotland), and newly named H3g1c,

defined by positions 13711 and 16399 (1.5 kya), is only found in Wales and Shetland. Other samples within H3g1 are mainly from Northwestern Europe with basal Danish samples and some sharing of lineages from Italy and Spain with the North. H3g2 (2.6 kya) is completely Irish and British. H3g3 (4.8 kya) and H3g4 (6.5 kya) on the other hand are found in Britain, France, the Netherlands and Russia, and in Belgium, Germany and Ireland, respectively. Samples directly branching off H3k (6.5 kya) are mainly from Italy and Spain (apart from one German sample). H3k1 (5.8 kya) has Spanish samples branching off, while H3k1a (2.8 kya) is only found in Britain. The British samples being nested within the Spanish ones, show a direct Atlantic connection, which is much more recent than the Early Neolithic, indicating that links along the Atlantic fringe continue throughout prehistory, although the age estimates are very rough. Further clusters branching off H3k are Spanish and Basque, German and Spanish. Other minor branches within 152 are Basque, Belgian, Danish, Dutch, German, Italian, Irish, Sardinian and Spanish.

Two Late Neolithic samples from Denmark and Germany (Allentoft et al., 2015; Haak et al., 2015) and one Early Bronze Age sample from Germany (Brotherton et al., 2013) can be found basal to H3b (9.5 kya). Again, this suggests that H3 was already well established and widespread during the Late Neolithic in Central Europe. Samples from England, Italy and Sardinia are basal lineages to H3b, as well as a small clade defined by position 11014, which is found in Britain, Ireland, France and Sardinia. All subclades of H3b belong to a cluster defined by position 16129. Basal to position 16129 are French, Danish and Italian samples. Directly branching from 16129 are samples from Denmark, England, Finland, Germany, Italy, South Tyrol and Spain. H3b1 (9.1 kya) is divided into H3b1a (3.7 kya) and H3b1b (7.9 kya). H3b1a is found in Belgium, Denmark, Ireland and Wales, and is similar to H3b1b, which comprises of Northwestern European samples from Denmark, France, Scotland and Wales, the latter two of which fall within H3b1b1 (4.9 kya). The overall distribution of H3b, and the partly very specific geographic distribution among Northwestern/Northern European countries, suggests a rapid movement throughout Europe and local evolution into the different clades of H3b, with Northeastern samples appearing to have arrived through Northwestern and Central Europe.

H3c (9 kya) contains mainly Spanish samples (including the Basque country) of which one dates to the Chalcolithic and a few lineages in Italy and

Northwestern Europe. two basal samples from Denmark and one basal ancient Chalcolithic sample from Spain (Günther et al., 2015). H3c1 (9.2 kya) includes one sample from Italy, while more recently diverged samples are from Britain and Germany. H3c2 (5.3 kya) is the biggest subclade and can be divided into H3c2a (2.2 kya), H3c2b (5.2 kya) and H3c2c (600 a). H3c2a is mainly found in the Basque country, with some exceptions found in Spain. H3c2b is only found in Britain and H3c2c is completely Basque. The distribution of these clusters suggest a migration $\sim$5.2 kya from Iberia along the Atlantic fringe towards the British Isles. One further cluster within H3c2 dates to 7.9 kya and contains both a German and a Spanish branch. H3c3 contains a basal ancient Spanish sample from the Chalcolithic (Mathieson et al., 2015) and a modern German sample, supporting a migration from the Southwest to Central and Northwestern Europe. Other clades or samples basal to H3c are from the Basque country, Denmark, France, Germany, Italy, the Netherlands, Portugal and Spain.

The cluster defined by a transition at position 16311 (dating to 7.6 kya, if a genuine clade) is divided into H3h (5 kya), H3m (3.3 kya) and H3n (3.1 kya). Basal to this clade are two Scottish samples from the Middle and Early Bronze Age (Olalde et al., 2018), suggesting that the origin of this clade is in Scotland, and that the initial development of the clade may have been in this geographic region. Modern samples directly branching off the root of 16311 are from Denmark, Finland, Italy and Scotland. H3h contains basal samples from Belgium and Italy. Samples directly branching off H3h are from Belgium, Britain, Denmark, France, Germany and Italy. H3h1 (1.7 kya) is a mainly Northeastern cluster with the majority of samples being from Finland, with the exception of one Russian and two Danish samples. H3h2 (3.6 kya) contains samples from Germany and Wales and H3h2a contains samples from Iran and Italy. This suggests a recent migration from Northwestern/Central Europe to the Mediterranean and Near East. Although the sample size in this case is fairly small it allows to distinguish back-migration from the North to the South from lineages that represent the initial source in the South. H3h3 (5.2 kya) is divided in H3h3a, H3h3b and an unnamed cluster. H3h3a (1.5 kya) is an Italian clade, H3h3b (1.7 kya) is found in Denmark, Germany, and the Netherlands, and the third clade (1.3 kya) is found in Finland and Sweden. H3h4 (6.1 kya) is found in Germany. H3h5 (1.1 kya) is found in Finland, Germany and Italy. H3h6 (3.6 kya) is found in the Basque country, Germany and Spain. H3h7 (2.8 kya) contains basal samples from Denmark and Germany. H3h7 is an extremely star-like subclade of H3h, as

all samples directly branch from H3h7 without any clustering. These samples are from Britain, Denmark, Germany and the Netherlands. H3m is mainly found in Ireland, whereas H3n is found in the Basque country and Spain.
The clade with the most samples belonging to one cluster and geographic region is the Sardinian clade (n=218) defined by position 93. Although this subclade dates to 6.6 kya, it could potentially have arrived with the Early Neolithic, dated archaeologically to ∼7.8 kya, followed by heavy drift in the small isolated population, since the branch emerges from the root of H3. This is supported by the unusually strong sharing of haplotypes within the subclade (and others in Sardinia). This drift, making the subclade extremely non-starlike, also renders the age estimate especially imprecise, and consistent with an Early Neolithic origin. The effect is even more pronounced in some of the smaller Sardinian-specific subclades of H3. There are several basal lineages in Spain (and one in Ireland) possibly pointing to an Iberian source, and one Italian tip lineage indicating recent migration to the mainland. This phenomenon has already been discussed in detail by Olivieri et al. (2017) and is one of the main arguments for a Southern European origin of H3. Although this data supports much more a Neolithic arrival, rather than the Mesolithic migration argues by Olivieri et al. (2017).
One Swiss Early Bronze Age sample falls within H3af (5 kya) (Olalde et al., 2018), which is mainly found in Germany, but also in Austria, the Basque country, Bulgaria, France and Spain. Smaller subclades of H3 that include British and Irish samples are:

- H3r (6.6 kya), which contains a basal Finnish sample, a Welsh clade dating to 2.6 kya, a Danish clade dating to 2.6 kya, and H3r1 (1.3 kya), which also contains an Italian sample;
- H3q (6.4 kya), which is mainly Scandinavian with samples from Sweden, Norway and Denmark, but including a clade with a French and an English sample;
- H3v (8.2 kya), which has a Late Neolithic Danish (Allentoft et al., 2015) and an Early Bronze Age sample from the Czech Republic within subclade H3v+16093 (Olalde et al., 2018) and generally comprises of an English, Irish and a Dutch basal sample, as well as some samples from Shetland, Germany, France, Belgium and Scotland;
- H3aa (5.7 kya), which includes Scottish, French and Irish samples;

- H3y (2.6 kya) contains German and a Polish basal sample and further includes British, Spanish, German and Basque samples that mainly all directly branch off the root;
- H3ao (6.5 kya), which contains Irish, German, Italian and Welsh samples and one German Early Bronze Age sample that belongs to H3ao2 (Brotherton et al., 2013);
- the cluster defined by position 16145 (9.7 kya), which contains British, Dutch and USA samples;
- H3ah (2.9 kya), which is mainly South European with samples from Spain, Italy and the Basque country, but also includes one Irish clade dating to 2.6 kya;
- H3ar (4.2 kya), which is a small branch with Italian and Spanish samples, including also one Welsh cluster (1.3 kya);
- H3z (8.4 kya), which is mainly Northwest/Central European found in Scotland, Poland, Britain, Denmark and France, but also in the Basque country and Russia;
- H3au (4.6 kya), which is divided into a Spanish/Basque cluster and a British branch;
- H3ag (6.1 kya), which is found in Belgium and Britain;
- the branch defined by position 16172 (3.5 kya), which contains samples from the Basque country, Ireland and Britain;
- H3ap (4.5 kya), which contains a basal English sample and has samples from Spain, USA and Britain directly branching off, as well as a small cluster of a Polish, a Danish and a Swedish sample.

Two small clusters, H3as (1.7 kya) and H3aq (1.3 kya), are only found in Ireland. Several British and Irish samples directly branch from H3. The phylogenetic analysis alone is inconclusive to determine the origin of haplogroup H3. Neither the tree structure or the distribution of H3 and its frequencies point towards one geographic origin, but most of the Northern European lineages had a source in Iberia. However, the analysis of the subhaplogroups, specifically those carrying only British or Irish samples, has given indications of when and from where lineages arrived in the British Isles and Ireland. Examples for Irish clusters are H3as and H3aq that directly branch off the root

of H3, and a Welsh clade within H3r that possibly arrived to Wales from Finland or generally from Scandinavia. Ancient British samples, such as the basal H3 sample from Neolithic Scotland (∼5.7 kya), support the arrival and establishment of specific H3 lineages on the islands.

C.3.2 Phylogeny of H6

For the phylogenetic reconstruction of mitochondrial haplogroup H6, a total of 456 published and unpublished sequences were used. 303 published samples consisted of 285 modern and 20 ancient mitochondrial genomes. The origin of the published data is shown in Table C.3. A total of 153 newly generated samples was included in the study, of which 31 from the British Isles and Ireland, five from Belgium, three were from France, 71 from Germany, seven from Italy, 14 from the Netherlands and 22 from Spain.

TABLE C.3: All published samples used for the phylogenetic reconstruction of haplogroup H6. Ancient sample numbers are indicated in bold.

The beginning of the dispersal of haplogroup H6 dates to 17.7 kya, before the LGM (Roostalu et al., 2007). It is the most frequent subclade of H in Central Asia, is found in the Arabian peninsula and is one of the oldest clades in the Near East and Caucasus. It is defined by the mutations 239, 16362 and 16482, and is divided into three subclades: H6a (12.6 kya), which accounts for 90% of the phylogenetic tree, H6b (10.6 kya), and H6c (3.4 kya). While H6a is mainly Central/Northwestern European, H6b is found in Israel, Palestine

and Armenia (50%), Italy (33%) and England (8%), with the British samples being most recent and nested within the Levantine/Armenian samples. H6c on the other hand is entirely Central/Northwest European, found in Germany, the Netherlands, Denmark, Slovakia, Poland, Wales, Scotland, Czech Republic, Norway and Sweden. The ρ age estimates and 95% confidence intervals for the major nodes are given in Table C.4. These age estimates especially for the European branches suggest a much older arrival and expansion within Europe than stated by Roostalu et al. (2007) of only 3.4 kya. Several Near Eastern lineages are interspersed within H6a, as well as Russian lineages. Basal to H6a, H6a1a and H6a1b are Yamnaya samples and H6a1b in addition also has a basal Corded Ware sample. This suggests a spread from the Near East to Russia in the Neolithic, possibly also with some lineages along the Mediterranean into Italy, but was then mixed in the Yamnaya/Corded Ware expansions into Europe at $\sim$4.5-5 kya. However, some European clusters look deeper, possibly originating in the Neolithic. Therefore, we might be seeing two conflated signals.
The major subclade H6a is clustered into H6a1 (10 kya) and H6a2 (4.6 kya), of which H6a1 includes the majority of the samples, and almost all of the ancient data. A Bell Beaker sample from the Czech Republic falls at the root of H6a. H6a1 is divided into H6a1a (6.5 kya) and H6a1b (8.1 kya), by far the two largest subclades within H6, which are about the same size. Whereas H6a1a branches in several clusters, H6a1b mainly consists of two bigger subclades and a few smaller ones. Of the six ancient samples belonging to H6a1a, four are from the Bronze Age (Germany (Brotherton et al., 2013), the Netherlands (Olalde et al., 2018), Poland (Olalde et al., 2018) and Russia (Mathieson et al., 2015)), one sample dates to the Roman period in England (Martiniano et al., 2016), while a Hungarian individual from the 10th Century AD was also identified as belonging to H6a1a (Neparáczki et al., 2017). The subclade of H6a1a1 (7.4 kya) is half Near Eastern and half European, H6a1a5 (2.6 kya) is an Eastern subclade found in Russia and Slovakia, and also subclade H6a1a4 (2.6 kya) is a North European/Eastern clade found in Denmark, Finland, Norway, Poland and Russia. All other subclades are almost entirely European, with most of the samples from Central and Northwest Europe. A Roman individual from England (Martiniano et al., 2016) was identified as H6a1a10 (4.2 kya). Within H6a1a no exclusively British/Irish clade was found. British and Irish samples either cluster with mainly Danish and German samples (as they account for the majority of the samples) or are directly branching off the root of H6a1a.

Polish and Russian samples are found at the root of H6a1b, while, with very minor exceptions, the rest of H6a1b is Northwest/Central European. The majority of ancient samples belonging to clade H6a1b are from the Early Bronze Age in England (Olalde et al., 2018), Poland (Allentoft et al., 2015) and Russia (Allentoft et al., 2015; Haak et al., 2015). This suggests that clade H6a1b was already widespread across the Eastern and Western extents of Europe during the Bronze Age, supporting the arrival of H6a with Near Eastern farmers during the Neolithic. Furthermore, an individual from the 10th century in Hungary belongs to this subclade (Neparáczki et al., 2017). H6a1b can be divided into the major clades H6a1b2 (4.2 kya), H6a1b3 (4.8 kya) and H6a1b4 (4.4 kya) plus several minor clades (including the recently occurring H6a1b1, which is found only in the Druze population (Behar et al., 2008)). The root of H6a1b2 has two samples from England (Martiniano et al., 2016) and Scotland (Olalde et al., 2018), from the Roman period and Middle Bronze Age respectively, as well as modern day Germany, Scotland and Spain. H6a1b2a (2.6 kya) is a British/Danish cluster, while H6a1b2e (3.3 kya) is almost completely Danish, with an Irish exception. Other small, recently occurring clusters of British/Irish samples branch directly off H6a1b2. Examples are an Irish/Scottish cluster (5.2 kya), two Shetland clusters, one of which can be dated to 400 years ago, and a Welsh cluster. Within H6a1b3, subclade H6a1b3a (1.9 kya) is entirely Welsh (excluding one sample from 'Britain'). This clade, and one Welsh individual that branches from the root of H6a1b3, are the only British samples within this clade, with the majority of samples being from Denmark and Germany. H6a1b4 had one mixed clade of Dutch, Irish and Italian samples (2.2 kya), with English, Irish and Shetland samples branching directly from the root. An Early Bronze Age sample from the Czech Republic also belongs to H6a1b4 (Olalde et al., 2018).

H6a2 includes a few Irish samples and is otherwise a mix of an ancient Russian from the Middle Bronze Age (Mathieson et al., 2015) at the root, and modern Basque, Danish, Iberian and Serbian samples. In the Near Eastern/European clade of H6b, one English sample is found in H6b1 (7.9 kya) on a branch dating to 3.9 kya, whereas, in H6c one Scottish and one Welsh sample can be found, indicating very recent minor gene flow from the Near East to the British Isles. Out of the 18 ancient samples in this clade, only two belong to H6b; a Late Bronze Age Armenian (Allentoft et al., 2015) and a Ptolemaic individual from Egypt (Schuenemann et al., 2017).

C.3.3 Phylogeny of H7

For the phylogenetic reconstruction of mitochondrial haplogroup H7, an overall total of 329 published and unpublished sequences was used. The samples comprising the published dataset are displayed in Table C.5. Only seven ancient samples have been reported to belong to haplogroup H7 so far, and all were included in the analysis. A total of 95 newly generated modern sequences, including two from Belgium, 20 from the British Isles and Ireland, four from France, 40 from Germany, four from Greece, 12 from Italy, one from Luxembourg, six from the Netherlands and six from Spain, were used in this study.

TABLE C.5: All published samples used for the phylogenetic reconstruction of haplogroup H7. Ancient sample numbers are indicated in bold.

Haplogroup H7 has an age estimate of 9.8 kya, is defined by the mutation at position 4793, and is divided into several large and small subclades. The biggest subclades are H7a (8.5 kya), H7b (5.9 kya), H7c (8.3 kya) and H7d (6.8 kya). Given the structure of the tree, the most likely origin of haplogroup H7 is Southeastern Europe. This assumption is based on basal Neolithic samples from Hungary and Bulgaria, suggesting a Neolithic dispersal into the Central and Eastern Mediterranean and into Central Europe, presumably with the *Linearbandkeramik* (LBK). The age estimates and 95% confidence intervals for all branches of H7 are given in Table C.6.

TABLE C.6: Rho age estimates and 95% confidence intervals of main nodes of the H7 phylogenetic tree.

Two ancient samples are found basal to H7. One sample is from Bulgaria (Mathieson et al., 2018) and the other from Hungary (Lipson et al., 2017), from the Eneolithic and the Middle Neolithic, respectively. They cluster with modern Danish and French samples. Another ancient sample from Chalcolithic Bulgaria (Mathieson et al., 2018) falls at the root of H7a1 (6.0 kya), together with modern Danish and German samples. A Neolithic sample from Croatia (Mathieson et al., 2018) is basal to H7c and a late Neolithic sample from Czech Republic (Olalde et al., 2018) is basal to H7d, together with an ancient sample from Germany dating to the Late Neolithic (Brotherton et al., 2013). A sample from the Unetice culture in Germany (Brotherton et al., 2013) falls at the root of H7h together with a modern sample from Spain, which are generally very few and possibly arrived with the Bronze Age or after. Similarly no ancient lineages have been reported from the British Isles or any other region of the Atlantic fringe.

Subclade H7a dates to ∼8.5 kya and is almost entirely European. The majority of samples within H7a fall into H7a1 (6.0 kya), and only two samples fall into H7a2 (2.6 kya). All other samples branch directly off the root of H7a. Subclade H7a1 is further divided into six larger subclades and two small subclades, with several samples just branching off the root of H7a1. H7a1c (2.3 kya) is entirely Central/Northwestern European, and is present in the British Isles (England, Scotland and Wales), Germany and the Netherlands. H7a1b (4.0 kya) is the largest of the subclusters within H7a1 and is mainly found in Denmark, England and Scotland, but also in Finland and Sardinia. H7a1a (5.3 kya) is entirely Italian, while sub-branch H7a1d (1.3 kya) is completely Danish. A very small and very recent clade is present in Britain and Russia.

Another very small clade dates to 2.6 kya and is entirely German. A small Danish/German clade dates to 2.6 kya, and a slightly bigger cluster dating to 5.2 kya is found in Denmark, Germany, Italy and the Netherlands.
Subclade H7b (5.9 kya) is found both in Europe and the Near East. It has two larger subclusters, H7b1 (4.8 kya) and H7b2 (4.4 kya), as well as several small clusters and branches that are all basal to the root of H7b. H7b1 is ∼40% Near Eastern (samples from Armenia and Israel), ∼40% South/Southeast European (samples from Italy, Greece and Sardinia) and ∼20% Central European (samples from Czech Republic and the Netherlands). The subclades of H7b suggest a Middle or Late Neolithic migration into the Near East and Central and Southern Europe.
The subclade of H7c (8.3 kya) is generally more South European. It is divided into one large subcluster, H7c1 (5.8 kya), and seven small clusters (H7c2 to H7c6 and two unnamed clusters). Around 50% of H7c1 are Italian and 10% from Israel, while the rest are from France, Germany, Russia, Scotland, Switzerland and Wales. One subbranch of H7c1 seems entirely British, with samples from Scotland and Wales, dating to 1.3 kya. Except for one German cluster (2.6 kya), all other subclusters of H7c are found in both North/Central and South Europe. H7c5 (2.6 kya) is a mix of Iranian and Italian samples. Generally, this cluster looks South European and suggests a spread to the Northwest of Europe during the Bronze Age.
The subclade of H7d (6.8 kya) is almost entirely Northwest European (∼ 77%), with other samples being from Belgium, Germany and the Netherlands (∼13%) or Spain. The largest subclade (1.8 kya), with ∼50% of the samples, is only present in Denmark, Norway and Shetland, with the samples from Shetland branching off recently from the Danish/Norwegian cluster. Subclades H7d1 (2.2 kya) and H7d2a (1.7 kya) are both Irish/British clusters. This suggests a Neolithic expansion, which is would be supported by the Middle Neolithic and Late Neolithic samples from Germany and the Czech Republic.
Most of the small subclades branching off the root of H7 are completely European, with only a very few samples from Asia, the Near East or Caucasus spread among them. H7f (3.5 kya) is another entirely British/Irish cluster, and an unnamed cluster dating to 1.3 kya, and identified by mutations 11689 and 14257, is only found in Wales. These British clusters seem to be very recent, possibly from the Iron Age.

C.3.4 Phylogeny of H8

For the phylogenetic reconstruction of mitochondrial haplogroup H8, a total of 124 published and unpublished sequences was included. The published dataset is given in Table C.7, and includes four ancient samples (three Armenian and one Moldovian) (Allentoft et al., 2015; Juras et al., 2017; Margaryan et al., 2017). The 78 newly generated sequences are from the British Isles (n=4), France (n=1), Germany (n=2), Greece (n=67, mainly due to a localised sampling/founder effect in Crete) and Italy (n=4).

TABLE C.7: All published samples used for the phylogenetic reconstruction of haplogroup H8. Ancient sample numbers are indicated in bold.

Country	Sample Number	Reference

Caucasian USA	2	1000 Genomes Project Consortium (2010)

Haplogroup H8 appears to be one of the oldest subhaplogroups of haplogroup H, with an age estimate of 17.6 kya. It is defined by four mutations: 709, 13101, 16288 and 16362, which divide the phylogenetic tree into three large subclades: H8a (5.5 kya), H8b (10.2 kya) and H8c (10 kya). The age estimates and 95% confidence intervals for all branches of H8 are given in Table C.8.

TABLE C.8: Rho age estimates and 95% confidence intervals of main nodes of the H8 phylogenetic tree.

Node	Rho	Standard error	Age	95% confidence interval
> H8	6.520	1.886	17,645	7418 - 28,405
>> H8a	2.100	0.900	5482	864 - 10,238
>>> H8a1	1.000	0.433	2585	388 - 4815

Continued on next page

Table C.8 – continued from previous page

Node	Rho	Standard error	Age	95% confidence interval
>> H8b	3.877	1.596	10,272	1928 - 19,029
>>> H8b1	2.833	1.106	7443	1718 - 13,371
>> H8c	3.692	0.944	9769	4800 - 14,884
>>> H8c1	1.667	0.745	4334	528 - 8236
>>> H8c2	0.600	0.346	1546	0 - 3315

Given the structure of the tree, the most likely origin of haplogroup H8 is in Southeast Europe, as the older subclades look South and Eastern European, H8b and H8c respectively. The much younger subclade H8a, is mainly Near Eastern and suggests a migration from Southeast Europe into the Near East ∼5.5 kya. This is further highlighted by the almost extreme separation of geographic areas based on the subclades of H8. H8a is the youngest subclade (5.5 kya) and includes an ancient sample from Armenia and the majority of its samples are from the Near Eastern Druze population. Its subbranch H8a1 (2.6 kya) is mainly found in Armenia (56%), including one ancient sample from the Late Bronze Age (Allentoft et al., 2015) and two from the Early and Late Bronze Age (Margaryan et al., 2017), and other samples are from Italy (22%), and Greece and Germany (each 11%). The subclade of H8b can be divided into the Asian/European Russian branch of H8b1 (7.4 kya) and a branch of solely Cretan samples. As the Cretan samples almost all have the same sequence it appears like a founder effect, especially as the branch is very recent. H8b1 consists of 18% Chinese and 82% Russian samples. A few other samples that belong to haplogroup H8b cluster separately and originate in France, Sardinia and Wales. Subclade H8b is the oldest cluster within H8 and extends into Siberia and China, with the exception of a newly reported Mediterranean clade found in Greece (Foody et al. in preparation). Subclade H8c has a basal Sardinian sample and can generally be divided into different European branches, suggesting a European origin. H8c1 (4.3 kya) is Central/Northern European, present in Denmark, Poland and Sweden. H8c2 is recent (∼1.5 kya) and entirely British, with samples from England, Scotland and Wales. Another fairly large subclade (23% of H8c) is completely South

European, present in Croatia, Italy and Spain, with the majority of the samples being from Italy. Four smaller branches are found in France and Spain, France and Wales, Germany and Italy, and Italy, respectively.
Among Asian populations haplogroups H6 and H8 are distinctly divergent from European haplotypes, which was stated to highlight a long-time separation of Asian and European H6 and H8 mtDNA genome pools (Loogväli et al., 2004). However, no deep Asian subclades could be identified in H6 to support this.

C.3.5 Phylogeny of H31

For the phylogenetic reconstruction of mitochondrial haplogroup H31, a total of 55 sequences was used. Of this, 39 are published data (see Table C.9) and 16 sequences (Belgium 1; British Isles 2; Germany 11; Netherlands 2; British Isles 2) are newly generated.

TABLE C.9: All published samples used for the phylogenetic reconstruction of haplogroup H31.

Country	Sample Number	Reference
British Isles & Ireland	8	Greenspan (*Direct Submission - Family Tree DNA - Genealogy by Genetics*) and Behar et al. (2012a)
Denmark	11	Li et al. (2014) and Raule et al. (2014)

Table C.9 – continued from previous page

Country	Sample Number	Reference
Caucasian USA	7	Greenspan (*Direct Submission - Family Tree DNA - Genealogy by Genetics*) and Just et al. (2014)
Unknown	4	Greenspan (*Direct Submission - Family Tree DNA - Genealogy by Genetics*) and Behar et al. (2012a)

Given the structure of the tree, the most likely origin of haplogroup H31 is Central or Northwestern Europe. This haplogroup is generally very small and not very frequent, given that it so far contains only 55 reported samples. To date, no ancient individuals have been designated as belonging to H31. It has an age estimate of 3.9 kya, which supports its recent origin, and also explains why it is not very common. It is defined by mutations 7930t and 10771, and is divided into three subbranches: H31a (3.6 kya), H31b (1.7 kya), and a branch defined by mutations at position 198 and 2789 (2.6 kya). The age estimates and 95% confidence intervals for all H31 branches are given in Table C.10.

TABLE C.10: Rho age estimates and 95% confidence intervals of main nodes of the H31 phylogenetic tree.

Node	Rho	Standard error	Age	95% confidence interval
> H31	1.491	0.443	3871	1604 - 6173
>> H31a	1.375	0.956	3567	0 - 8564
>> H31b	0.667	0.333	1719	34 - 3422

Subclade H31a is the largest of the subclades and of fairly mixed European

origin, with samples from Denmark, Netherlands, Northern Wales, Scotland and Southeast England. Subclade H31b is much smaller with samples from England, Germany, Netherlands and Norway. The yet unnamed and smallest third subclade, defined by positions 198 and 2789, solely consists of samples from Denmark and Sweden, suggesting a Scandinavian origin. It is not possible to determine a more precise geographic origin for H31a and H31b, as they both have a mixed distribution within Northwestern and Central Europe. Based on the origin of the majority of basal samples from H31, a general origin within Denmark or Germany could be argued for, with a main spread into the British Isles and the Netherlands. Haplogroup H31 appears to have spread from Scandinavia across Northern Europe, possibly during the Bronze Age dispersals.

C.4 Conclusion

The phylogenetic reconstruction of specific sublineages of haplogroup H has facilitated a more detailed picture of the distribution and origin of the haplogroup. Several lineages can be traced to their origin, and the inclusion of ancient data in the reconstruction can help to understand arrival times of specific lineages, as well as the entire haplogroup H itself. Due to the large scope of this project, the number of people involved, and the time it takes to reconstruct all phylogenetic trees of all haplogroup H lineages, this chapter unfortunately only shows a small part of the overall research, which should show a lot more details of the overall evolution of haplogroup H. However, the presented phylogenetic analyses already give a lot of information on the individual subhaplogroups. As the work on this project is still ongoing, the full reconstruction and Founder Analysis of haplogroup H are still to be completed. The results of these analyses should throw light onto the haplogroup H enigma, and help us to understand the origin of H and its arrival and spread in Europe.

Appendix D

Negative control analysis and DNA damage patterns

D.1 Negative controls

To assess anti-contamination measures, negative controls were introduced during each stage of sample processing for all samples. An air control and a water control were introduced during the drilling stage. The air control consisted of an empty 1.5ml Eppendorf tube with an open lid, which was either placed for one hour in the cleaned work area between sample drilling (TCD approach) or placed during drilling of one random sample within the drilling hood (University of Huddersfield approach). For the water control, 2ml of $dd H_2O$ were shaken, minus the steel ball, inside a metal shaker in the Mixer Mill (Retsch MM400). 1ml of the water control then went through the whole extraction process.
None of the controls that accompanied the three samples prepared at TCD were sequenced. Controls introduced during the extraction process at the University of Huddersfield were quantified using a Qubit 3.0 Fluorometer, and the DNA content of all controls was too low to be measured. However, negative controls from the extraction, USER treatment step, and library amplification step were sequenced alongside the samples on an Illumina HiSeq 2000 (NBAF Liverpool). For the sequencing runs undertaken on the Illumina HiSeq 4000 (Macrogen, South Korea), one extraction control and one library control were sequenced alongside the samples. The sequencing results for all controls are displayed in Table D.1.
The mitochondrial contamination of all controls was estimated to be lower than 0.001%.

TABLE D.1: Sequencing results of the controls from all sequencing runs.

	Control ID	No. of mapped reads	Mismatches	Mean mapping quality	Mean coverage	Std coverage
Liverpool	USER	82	9	6.47	0	0.0012
	Negative	7	1	0.61	0	0.0004
	Library	0	-	-	-	-
Macrogen	Library	369,809	115,634	35.58	0.0061	0.0795
	Extraction	62,025	25,066	35.57	0.0008	0.0291

D.2 DNA damage patterns

All analysed samples were treated with uracil-DNA-glycosylase (UDG) during the library preparation, which reduces the number of ancient DNA errors by cleaving uracils (deaminated cytosines). Therefore, the samples displayed reduced damage patterns, which were observed using mapDamage (Jónsson et al., 2013) and bamdamage (Malaspinas et al., 2014).

D.3 Sequence length distribution

The analysed samples displayed a sequence length distribution with a peak between 45-55 bp for each sample. Therefore, all samples display sequence lengths previously reported from ancient samples displaying an average sequence length of less than 100 bp (Shapiro et al., 2014) . A peak at 100 bp could be observed as well, representing all sequences greater than this length that were truncated in their sequencing runs.

D.4 Gamba calculations

As expected, the number of reads from the controls aligning to the human reference were much higher for the blanks run alongside the samples sequenced on a HiSeq 4000 (Macrogen, South Korea) than the number of reads found in the controls sequenced on a HiSeq 2500 (NBAF Liverpool, United Kingdom). Gamba calculations Gamba et al. (2014) were used to estimate the contamination of these blanks, and thus estimate the amou7nt of possible contamination across all samples. An overview of the number of raw and mapped reads of the samples on two lanes (lane one and lane three) can be found in Tables D.2 and D.3. The calculations of the contamination fraction of the lanes including controls (lane one and lane three) can be found in Tables D.4 and D.5.

The number of reads alignable to the human reference genome obtained for the controls were compared to the number of reads obtained for the samples

run on the same lane, and normalised by the total number of reads obtained in each HiSeq run, in order to estimate the laboratory contamination at each stage. This contamination estimation followed Gamba et al. (2014), calculating the contamination fraction (C) as follows: $C = (R_b/TV_b)/(R_s/TV_s)$ with R_b denoting the number of control reads aligning to the human genome, R_s the number of reads aligning to the human genome for the sample analysed in parallel with the control, T the total number of reads obtained in the specific HiSeq run and V the volume added to the pool loaded on the sequencer for controls (V_b) and samples (V_s).
For the two lanes (libraries K1-K12 and K25-K36) I calculated a C value of 0.9145% and 0.4951%, respectively. In comparison Gamba et al. (2014) reported 0% and 0.5%. The maximum number of reads for a blank in Gamba et al. (2014) was 282, which equates to ∼6316 reads on a HiSeq machine based on the 22.4 fold difference in read numbers. However, a lot also depends on the number of samples run per lane.

TABLE D.2: Number of raw reads and mapped reads per sample on lane one.

Library name	DNA ID	No. of raw reads	No. of mapped reads
K1	KD039	75,917,571	11,945,233

All mapped reads for 11 samples / (total reads per lane x 11/12)	0.0223
Contamination fraction (C)	**0.4951**

Appendix E

Sex determination of low coverage samples

A number of samples had a very low genome coverage and no genetic sex could be assigned based using the script by Skoglund et al. (2013). Therefore, the number of reads with "Mapping Quality 30" was plotted against the chromosome length. The number of reads with "Mapping Quality 30" mapping to the X-chromosome were compared to the number of reads which aligned to chromosome 7 (as they are of similar length) and normalised by the length of the reference sequence following Skoglund et al. (2015). Two better coverage samples, one female and one male individual, were plotted alongside, and the Skoglund score was calculated as comparison for the low coverage samples.

Equations to calculate the percentage of single or double copies of chromosome X are given in the following:
KD001 - male control - Rosemarkie:

$$(382,142/155.270,560)/(835,025/159.138,663) = 46.9\% \tag{E.1}$$

CE005 - female control - Oakridge:

$$(903,995/155.270,560)/(1.038,778/159.138,663) = 89.2\% \tag{E.2}$$

KD039:

Appendix G

Y-chromosome haplogroup identification

The complete lists of all derived mutations of Y-chromosome predictive markers used in Yleaf are given in the following tables. Mutations at the first or last three bases of a sequence read were excluded, as well as mutations with a quality score of less than 30.

G.1 Strathglebe

TABLE G.1: Yleaf output of KD026, filtered for derived alleles with call percentage 100, excluding positions with low coverage and at the last three bases of reads.

Additional data

I.1 Carsington Pasture Cave

Carsington Pasture Cave (CPC), Derbyshire, was excavated by A.T. Chamberlain in 1998-1999. It contained 34 human burials, consisting of 16 adults and 18 juveniles, of which four mandible/maxilla fragments were given to Dr. C.J. Edwards for aDNA analysis.

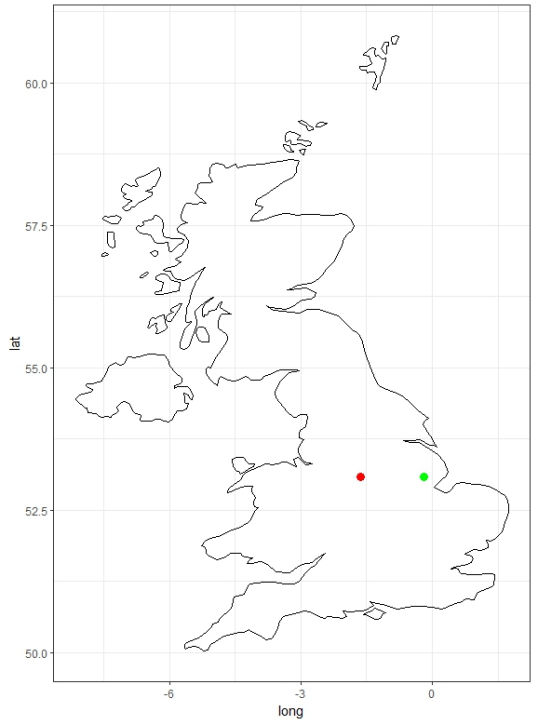

FIGURE I.1: The location of the Carsington Pasture Cave (red) and Beeston Tor (green) within the British Isles.

16 samples were later given to Dr. Tom Booth at the Natural History Museum, London. The human remains found in the cave dated to the Neolithic and Iron Age, and three of the four mandible/maxilla samples were analysed in this study.

TABLE I.1: Archaeological information of the Carsington Pasture Cave and Beeston Tor individuals analysed.

DNA code	DNA sample	Site information	Sample code	Age	Sex	Skeletal element(s)	Era	Date (uncal. bp)/ (Dating lab #)
CE001	LRM2	Carsington Pasture Cave, Derbyshire	CPC98-312	>45 years	M	mandible (with LM3, RM2 and RM3)	early/middle Neolithic	4795 ± 29 (OxA-28867)
CE003	UM2	Carsington Pasture Cave, Derbyshire	CPC02-Y-062	17-25 years	M	maxilla with teeth	early Iron Age	2460 ± 30 (OxA-29233)
CE004	LRM2	Carsington Pasture Cave, Derbyshire	CPC98-002	35-45 years	M	mandible with teeth	middle Iron Age	2240 ± 24 OxA-28865
CE002	ULP2	Beeston Tor, Staffordshire	BCX09-136	17-25 years	x	left maxilla (with P1, P2, M1, M2 and M3)	Bronze Age/ Iron Age	x

The Neolithic individual (CE001) was determined as genetically male, with T2c1d1 as his mitochondrial haplogroup. This is the same mtDNA haplogroup as determined for a Neolithic sample from Carsington Pasture Cave reported in the major Bell Beaker study this year (Olalde et al., 2018), and it is likely that the two samples belonged to the same individual. Haplogroup T2c1 comprises of the majority of T2c, and originated in the Near East ∼18.5 kya and dispersed into Europe ∼10 kya (Pala et al., 2012). It is most common in the Near East, specifically in the Gulf region, and is found in the Levant and Mediterranean Europe, however, it has a low frequency in the rest of Europe (Pala et al., 2012). Other reported Neolithic individuals belonging to this haplogroup were found in Holm of Papa, Westray North, Orkney, Scotland (Olalde et al., 2018), France (Olalde et al., 2018), Germany (Lazaridis et al., 2014; Haak et al., 2015), Hungary (Lipson et al., 2017), and Iran (Broushaki et al., 2016). The Early Iron Age CPC individual (CE003) was determined as female and belonged to mitochondrial haplogroup X2b4a1. Although ancient individuals reported to belong to X2b4 were found in Bell Beakers from France (Olalde et al., 2018), Late Neolithic and Alemanni Germany (Haak et al., 2015; O'Sullivan et al., 2018), and Bell Beakers in the Netherlands (Olalde et al., 2018), the mitochondrial haplogroup X2b4a has not been reported from the British Isles previous to this study. Alongside this Early Iron Age individual, one of the Anglo-Saxons from West Heslerton had haplotype X2b4a, and so these two people are the first evidence for this haplogroup in ancient periods in Britain. One-third of the European sequences within X2 are encompassed by subclades X2b and X2c, with X2b also including some North African sequences (Reidla et al., 2003). The diversity of subclade X2b in West Eurasia and North Africa is consistent with a post-glacial population expansion (Reidla et al., 2003). The Middle Iron Age individual (CE004) was a male and belonged to mtDNA haplogroup H10b, which has not yet been reported in ancient individuals. Ancient individuals belonging to H10 or other subclades of it have been reported from Bell Beakers in the Czech Republic (Olalde et al., 2018), Neolithic Croatia (Mathieson et al., 2018), Neolithic, Bell Beaker and Alemanni Germany (Brotherton et al., 2013; Olalde et al., 2018; O'Sullivan et al., 2018), and Late Bronze Age Latvia (Mittnik et al., 2018).
Although the Y-chromosome coverage was very low and only few Y-chromosome haplogroup predictive markers were found, it was possible to type the Neolithic individual as haplogroup I, whereas the Middle Iron Age individual was most likely R1b, possibly subgroup R1b1a1a2a1a. When comparing the Neolithic with the published data from the same individual (Olalde et al.,

2018), the predicted haplogroup was I2a2a1a1a.

I.2 Beeston Tor

An individual (CE002) from Beeston Tor, Staffordshire, England, from the Bronze Age/Iron Age was sequenced to a very low coverage of only 0.002x, which made sex identification inconclusive, and genome-wide analysis impossible (due to the low number of overlapping SNPs <10,000). However, the mitochondrial genome was sequenced to 1.2568x coverage, which was enough to assign the individual to mitochondrial haplogroup U8b. Mitochondrial haplogroup U8b is an eastern European haplogroup, found in the Neolithic in Croatia (Mathieson et al., 2018), the Czech Republic (Olalde et al., 2018), Hungary (Lipson et al., 2017), Scotland (Olalde et al., 2018), and the Ukraine (Mathieson et al., 2018). It has also been found in Neolithic Jordan (Lazaridis et al., 2016) and Turkey (Mathieson et al., 2015). In the Chalcolithic/Bronze Age, individuals belonging to subclades of U8b have been found in Armenia, the Republic of Artsakh (Margaryan et al., 2017), as well as in the Czech Republic (Lipson et al., 2017) and Hungary (Olalde et al., 2018). Furthermore, it has been reported in an individual from the Ptolemaic period in Egypt (Schuenemann et al., 2017).

Appendix K

Milla Skerra - Supplementary Information

K.1 Introduction

The Glasgow University Archaeological Research Division (GUARD) excavated an eroding coastal site between 2004 and 2007 at Sandwick on Unst in the Shetland Isles (Figure K.1).
During this excavation the remains of a partly truncated building of later prehistoric date were revealed. While excavating the building, an inhumation burial was also discovered, which had been cut through windblown sand that sealed the building after its abandonment. The burial was radiocarbon dated to AD 130-390 (SUERC-10745), which falls within the Scottish Iron Age. The individual was identified as a 50-60 years old male at time of death. Although there was slight surface erosion of the bone, the preservation of the skeleton was good. The individual was buried with small grave goods such as a polished disc of cordierite talc schist, as well as yellow beads on a copper-alloy spiral ring.
The burial being close to an abandoned settlement appears to be a widespread practice during the later Iron Age of placing articulated bodies into or around ruins of buildings across the North and West of Scotland. This practice points to a shared concept that indicates connections between the dead and ruined buildings, joining the people to their lineages. Occasional burials along the foreshore of Sandwick are also known. On the same beach, other remains were found in short cists. Another burial was found slightly further north in a kerbed cairn dating to 370-520 cal AD (GU-1291).
Viking longships from Norway arrived on Unst in the 8th century AD. Including Scandinavia, Unst has the highest density of early rural longhouses known in the Viking world. As the obliteration of indigenous toponymy in the Northern Isles indicates that the Viking settlement involved the gradual

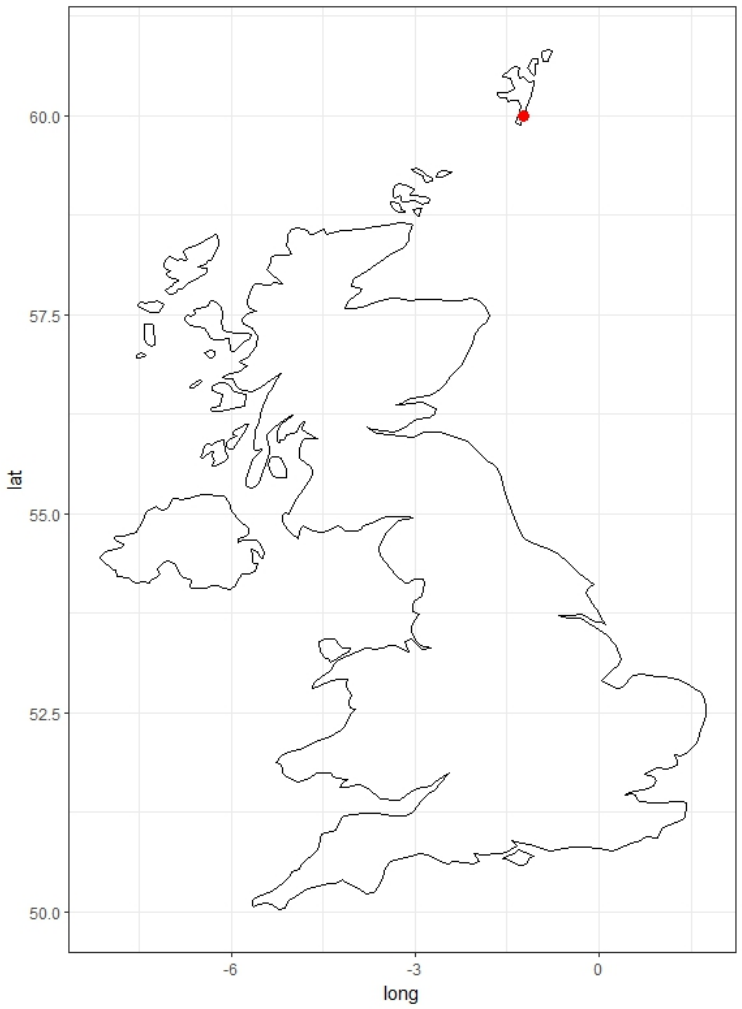

FIGURE K.1: Location of Milla Skerra, Sandwick, Shetland, within the British Isles.

destruction of the indigenous population, rather than intermarrige or cultural assimilation (Smith 2003), the genetic analysis of the male skeleton from Milla Skerra might shed light on the population dynamics in Shetland during the first millenium AD.

K.2 Materials and Methods

The petrous bone was sampled for DNA extraction. The sampling procedure and NGS library preparation followed as described in Chapter 2. The sample was single-indexed for 100bp paired-end sequencing on a HiSeq4000 (Macrogen, South Korea). Bioinformatic processing followed all steps as described in Chapter 2.

K.3 Results

The endogenous content of the sequenced sample was 6.76% and the overall genome coverage was 0.0131x and for the mitochondrial genome 3.1477x. Sequencing results are displayed in Table K.1.

TABLE K.1: Sequencing results of the Milla Skerra individual.

ID	KD073
Endogenous content in %	6.76
Duplication rate in %	0.1384
Genome coverage	0.0131
Std. genome coverage	0.1339
Mitogenome coverage	3.1477
Std. mitogenome coverage	3.6466

K.3.1 Dietary stable isotope analysis

In order to identify the type of diet the Milla Skerra individual consumed over its lifetime, dietary stable isotopes were analysed (Figure K.2).

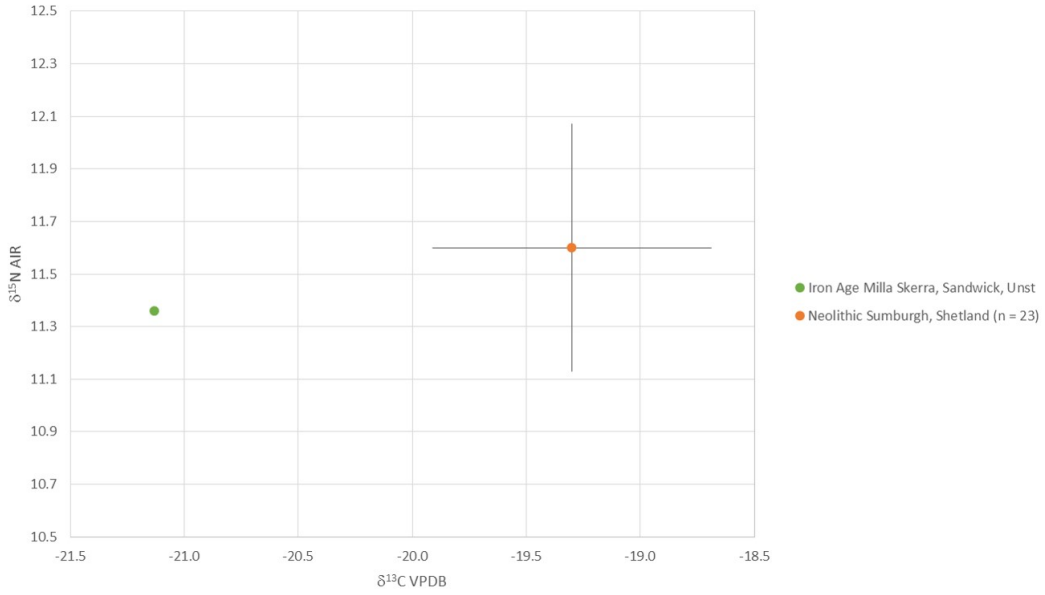

FIGURE K.2: Dietary stable isotope data of the Iron Age individual from Milla Skerra.

K.3.2 Genetic sex determination

The genetic sex could not be assigned using the Skoglund script, therefore a karyotype plot was created to see if an indication for the genetic sex could be

made based on the chromosome length and the number or reads per chromosome. Additionally, the percentage of reads of chromosome X was calculated as 70.3%.

K.3.3 Uniparental marker haplogroup assignment

The individual was found to have all the defining mutations for haplogroup J1b1a1.

TABLE K.2: Mitochondrial DNA haplogroup of the Milla Skerra individual and mutations identified.

Sample	Haplogroup	Average coverage	Polymorphisms
KD073	J1b1a1	3.1477x	73G 146C 152C 263G 279C 709A 750G 1438G 1888A 2706G 4216C 4769G 4917G 5187T 6261A 7028T 7873T 8697A 8860G 10463C 10822T 11251G 11719A 11812G 11914A 13368A 14233G 14766T 14905A 15326G 15452A 15607G 15928A 16126C 16292T

The Y-chromosome haplogroup prediction resulted in only two predictive markers, namely M9370 and Z40372, were found.

K.4 Discussion

The shot-gun sequencing of the Milla Skerra sample resulted in a very low coverage genome of 0.0131x. After pileup calling of variants against the Lazaridis reference dataset, only ∼8000 SNPs were called. This is too low for any genome-wide analysis, therefore, no principal component or ADMIXTURE analysis could be performed. Furthermore, the number of reads was too low to securely determine the genetic sex, and none of the sexing methods gave any conclusive result.

As the osteological sex determination indicated a male individual, Yleaf was run to see if predictive SNPs could be found. Only two predictive markers were found in this sample, M9370 and Z40372. In order to analyse the Y-chromosome for the paternal haplogroup and the whole genome for genetic admixture, further sequencing of this sample is required. A better coverage of the genome would allow to analyse this sample alongside other individuals from the Viking era and compare it to Anglo-Saxon and Romano-British

genomes.

The Milla Skerra individual was assigned to belong to mitochondrial haplogroup J1b1a1. The clade of J1b1a1 encompasses the clade of J1b1a1a, which was determined to be the mitochondrial haplogroup of the previously discussed Rosemarkie individual (see Chapter 6. Haplogroup J1b1a is the only European clade within J1b (Pala et al., 2012).

The Iron Age Milla Skerra individual had a different diet from the Neolithic individuals from Sumburgh in Shetland, which is interesting as both sites are close to the coast. The trophic level of both the Milla Skerra individual and the individuals from Sumburgh were very similar, suggesting a similar amount of protein intake into their diets. However, the $\delta^{13}C$ values are very different, most likely because the Neolithic individuals from Sumburgh were eating a diet that relied more heavily upon fish.

Appendix L

Frequency tables of modern data
